My mind must be made on a different pattern from Prof. Milne's, for the necessity of the substratum as a background for phenomena does not appear to me at all self-evident. I find myself capable of doubting the possibility of existence of the army of equivalent observers, of doubting their significance for natural philosophy or anything else if they did exist, and of doubting the ability of stars and planets to know where the decisions of the substratum conference required them to be. I have a conviction that, like Adam in Blanco White's sonnet, I should not have known that the universe contained numerous bodies outside the earth if no one had observed them. I am not persuaded that Einstein "still relied on an empirical assumption—the constancy of the speed of light—in his derivation of the Lorentz formulae, not realising that the same ideas could be developed further so as to dispense with this assumption". It seems to me that this "empirical assumption" was nothing more than a statement of the time-scale adopted in relativity theory, just as Newton's First Law of Motion is a statement of the time-scale adopted in classical theory, and the substitution for it of an animistic philosophy in which the same constant is adopted as a convention by hypothetical observers instead of as a unit of measurement by actual ones seems to me neither an improvement nor a logical necessity. In short, while I am perfectly ready to adopt Prof. Milne's postulates as an axiomatic basis for physical theory if he can show that they lead to a simpler and more comprehensive correlation of experience than any other, and very much hope that he will be able to give his voluminous and elegant mathematical work some acceptable meaning, I retain sufficient imagination to conceive, and liberty to choose, postulates of very different character.

Finally, I find it impossible to understand what Prof. Milne means by his claim that he has said "exactly what is meant by a quantitative statement in terms of operations that could be actually carried out". Having, through the kindness of the General Electric Co., recently acquired the charge of a particularly bright lamp, and having access also to a Riefler clock and other ticking devices, I felt myself in a position to become an "equivalent observer", and began to consider how I should set about deriving the laws of the universe. The first step was to send a beam of light to another such observer, but, having noted the instant by the clock at which my lamp was uncovered, and, just to emphasize its arbitrariness, decided to move that c be given the value $2 \cdot 99796 \times 10^{10}$, I found I could get no further, for the next observer failed either to pick up my beam or else to send it back to me. This, perhaps, was only to be expected, since he was theoretical, ideal, abstract, but it left me in a dilemma: I could not communicate with an equivalent observer since he did not exist, and it was useless to communicate with a possibly existing observer (say on Mars) since he was not equivalent. My clock jeered at me in the old Greenwich rhythm, and I could not even begin to measure the first distance and epoch.

What was to be done? In all sincerity, I do not know. I can understand that it *would* be possible "in principle" for me to carry out Prof. Milne's instructions if the theoretical observers existed and were complaisant, though I am not so clear why, if he can reduce the appeals to quantitative experience to zero, he makes this superfluity a principal guiding motive. But the fact is that there is still a great deal about the universe that I do not know and would very much like to know. I am prepared to accept any indirect procedure which can be shown to yield the same result as the ideal one, but Prof. Milne has described none and I can imagine none myself. So I remain unable to understand what is meant by the claim that the meaning of quantitative statements has been stated "in terms of operations that could be actually carried out".

HERBERT DINGLE.

BUDGETARY AND DIETARY SURVEYS

A WHOLE-DAY Conference of the Nutrition Society was held on February 5 at the London School of Hygiene and Tropical Medicine to discuss "Budgetary and Dietary Surveys of Families and Individuals". The meeting was devoted in the main to a consideration of different methods of conducting such surveys and their comparative value.

The Society is doing valuable work in bringing together social workers and experts interested in different aspects of the subject of nutrition and able to speak from knowledge and experience. Thus each comes to view the problems which arise with a due sense of proportion and to correct the impression which might otherwise be formed that one particular approach to a solution is all-important. As Sir John Orr, who presided, pointed out, food will occupy a key position in post-war reconstruction. The Prime Minister put it first in his Guildhall speech. It is essential, therefore, that all the relevant facts should

be assembled in good time to put before legislators. Papers were contributed by Dr. E. R. Bransby (Ministry of Health), Mr. A. G. Jones (Ministry of Food), Mr. L. Moss (War-time Social Survey), Mr. F. Le Gros Clark (Children's Nutrition Council), Prof. A. L. Bowley (Institute of Statistics, Oxford), Prof. Major Greenwood (London School of Hygiene and Tropical Medicine), and Mr. D. Caradog Jones (University of Liverpool).

A fundamental question was raised at the outset by Mr. A. G. Jones: Are household budgets suitable instruments for the assessment of nutritional welfare? In his very competent analysis of the difficulties encountered in such inquiries, a number of points were stressed to which the Conference returned again and again in different contexts. The following are typical examples: (1) If the household is the unit of measurement, the food consumed may be adequate for the household as a whole but not adequate for every individual in the household. (2) The food consumed may be adequate in the week sampled, but not adequate in subsequent weeks. (3) To measure the food actually consumed in a selected week, account must be taken (*a*) not only of the food bought that week, but also of the food saved from any previous week or kept for consumption in any future week; (*b*) of home-grown and home-made food, and of food obtained free of charge; (*c*) of food eaten from home and of food eaten by visitors; (*d*) of food wasted and food values reduced in preparation and cooking. (4) Accuracy in the conversion of food, raw and cooked, of which only the price or weight may be known, into terms of nutritional value is not easy to achieve. (5) The food requirements of individuals vary with age, sex, and other less obvious factors.

Although there are ways of meeting such difficulties, it is clear that they call for an exceptional degree of willing co-operation on the part of housewives if they are to be met at all satisfactorily. It was not surprising, therefore, that some speakers expressed doubt whether nutritional surveys of families could be of any real value. This, as Dr. Bransby pointed out in an illuminating paper on studies of food consumption, is to misinterpret the function of family surveys. Their purpose is not to provide information on individual intakes, but "to enable estimates to be made of the food consumptions and adequacy of nutrient intakes of groups of families according to such factors as income and family size". Two distinct methods were used experimentally in surveys of this kind during the early part of the War by the Ministries of Food and Health: namely, the precise or weighing method, and the log book. As a result of this experience the first method was discarded as too slow and laborious, and the log book method has now been in use with success for nearly four years. Another serious objection to the weighing method is the involved technique, which makes it practically impossible to obtain the co-operation of a properly selected random sample of housewives. Dr. Bransby and others thought that dietary surveys should become part of wider and more detailed investigations, to which clinical, biochemical, sociological, and other data could be related. For this it would be essential to make the individual the unit of inquiry. With experience thus accumulated it might be possible to ascertain the precision that can be attached to nutrient intakes calculated from prepared food tables.

Prof. Greenwood drew a distinction between nutrition studies of stable groups and those of unstable groups in the population. The fundamental aim of all such studies is to discover what he called "the energetic cost of life and work". It has been long since established and repeatedly confirmed by experiments in widely different areas that, for a stable group, the normal daily calorie intake is in the neighbourhood of 3,000 per man, with a coefficient of variation of 10–14 per cent. Accordingly, in his opinion, the most valuable type of study to be undertaken now is that of an unstable group where danger to health or growth is threatened. If the mean calorie intake falls continuously below a critical value of 2,600, or if the coefficient of variation rises much above 14 per cent, disaster might almost be predicted within the observed group. Two recent surveys of mining households in the north of England were instanced, where the calorie average was 2.830–2,860 with a coefficient of variation of about 20 per cent. Prof. Greenwood ended by stressing the necessity for a rigid application of the random sample principle in nutritional surveys.

The problem is to secure a random sample, if scientifically precise methods are to be used in determining individual needs and consumption, especially in view of the fact that among the very poor, whose need is greatest, precision is most difficult to achieve. Moreover, the psychological reactions of the individual observed may also prejudice the results by their influence on veracity or consumption. There is clearly need for experiment in this field, with small but carefully chosen groups in different parts of the country and different strata of the community, to discover the best methods of approach and the most promising technique to adopt. The results of work recently done by the Ministry of Health in collaboration with the Ministry of Food and the War-time Social Survey, of which Mr. Moss gave some account, are both interesting and useful, but this has been related primarily to administrative needs: the methods used were not exact enough for a scientific study of nutritional problems.

In contrast, the Conference had an academic exposition by Prof. Bowley of the fitting of a straight line to a set of statistics relating expenditure on a particular commodity to the total available income in a suitably selected sample of households. Such research clearly has an important place in the development of knowledge about nutritional needs and habits. Attention was directed also to the actual and calculated range of variation on either side of the average expenditure within a selected sample. In the discussion which followed, Dr. Bradford Hill remarked that there has been too great a tendency to confine records of expenditure and consumption to averages of the observations sampled. He put in a plea for the more general publication of the complete frequency distribution, so that the amount of dispersion about the average might be estimated. He took a sensible middle line between those who only favoured small samples, on the ground of greater accuracy, and those who favoured large because the small were seldom in effect random. Incidentally, Dr. Yates of Rothamsted, who had just returned from the Continent, expressed the opinion that nutrition surveys in occupied countries would be of considerable help to the administration immediately after the War if carefully planned now. He and others urged the need for greater uniformity in the conduct of surveys and the treatment of data; comparable results can only be obtained by co-ordinated team work.

The final contribution to the general discussion was a series of tables concerning human needs and related vital statistics, presented by Dr. B. Woolf of the University of Birmingham. He had prepared lantern slides beforehand, and his running commentary on each table of figures thrown on to the screen introduced a touch of light comedy into the proceedings. It was not perfectly clear whether his remarks were to be taken seriously, for he questioned in turn estimates made by Sir William Beveridge, Mr. Rowntree, Prof. Bowley, the British Medical Association Committee on Nutrition, and others, hitherto accepted as authoritative. The present writer, in the course of a paper comparing the relative amounts of family expenditure allotted to food and other commodities, had applied a slightly amended estimate of Sir William Beveridge's subsistence scale to determine the bare cost of living of a family of four persons. The estimate for food, criticized by Dr. Woolf, was based on the scale recommended by the League of Nations Technical Commission on Nutrition as interpreted in the Beveridge Report.

As Dr. Bransby pointed out later in discussion, practical and reasonable diets were drawn up in conjunction with dietitians to conform to this scale, and the diets were costed on the basis of the Ministry of Labour food prices in 1938. If such figures are not accepted, where do we stand ? In the same paper an attempt was made to focus particular attention on a practice which is perhaps not generally recognized. In estimating a subsistence standard, only the cost of food is based strictly on need ; the other figures are determined by what is customary rather than by what is strictly proved from first principles to be necessary. The cost of items other than food in the above-mentioned paper was, in fact, closely related in each case to what the poorer families in the towns of Great Britain actually do spend (not what hard-hearted statisticians think they ought to spend) on these items, judging by the best available evidence, namely, the extensive and representative sample of household budgets collected by the Ministry of Labour in 1937–38.

Sir John Orr, at the end of the meeting, reviewed the difficulties involved in making dietary surveys. On the basis of experiment there could be no doubt as to the benefit children received when protective foods were added to their diet, and the British Government is committed to the task of improving nutrition to an optimum health level. The desired standard could not be reached for some years. We should need to produce more food ourselves and to import more. The whole problem of the organization of agriculture and the prices of foodstuffs must be settled. How much will the country have to pay the farmers to produce what is necessary ? Furthermore, in estimating needs we must not be too academic. People cannot be blamed for choosing to spend on other pursuits, to enliven dreary lives, part of the weekly income which might otherwise be spent on food. The solution, he suggested, is so to adjust finance and wages that there would be enough money for all to buy food and other necessities and to leave a reasonable margin for pleasure.

The Conference is to be resumed in May to discuss the results of the analysis of diets consumed in institutions, also various methods used in the preparation and cooking of food, and the laboratory assessment of the nutritional value of meals.

D. CARADOG JONES.

OBITUARIES

Prof. Yandell Henderson

YANDELL HENDERSON, whose death at the age of seventy occurred on February 18, held in succession the chairs of physiology and of applied physiology at Yale University. Although his investigations embraced many aspects of the physiology of the circulation and respiration, he will probably be best remembered for his advocacy of the value of carbon dioxide as a respiratory stimulant in a variety of clinical disorders.

Early in his career, Henderson's attention was attracted to the problem of surgical shock and to the failure of the circulation associated with this. This, he saw clearly, must be due to failure of the venous return to the heart, but the generally accepted idea that this was dependent on failure of the vasomotor control of the arterioles afforded him no adequate explanation. He noticed, too, that the venous return and the output of the heart could be greatly diminished by undue reduction of the carbon dioxide content of the body brought about by over-ventilation of the lungs, and that the venous congestion in the alimentary tract, and the paralysis of normal peristaltic movement when the abdomen was opened and the intestines exposed, was dependent on serious loss of carbon dioxide from the tissues by diffusion into the surrounding air. He was thus led to develop his theory of a veno-pressor mechanism independent of, but supplementary to, the arterial vaso-motor system, a mechanism which was dependent on the maintenance of an adequate concentration of carbon dioxide in the tissues. Although at first he was inclined to think that the explanation of this mechanism might be found in the effect of carbon dioxide on the veins, he soon developed a much wider theory, namely, that the maintenance of an adequate venous pressure was essentially bound up with the maintenance of normal reflex muscle tonus, and the support given by this to the veins and capillaries; and that anything which interfered with muscle tonus must lead to failure of the venous return to the heart.

Henderson had a profound admiration for J. S. Haldane, but it was not until 1910 that the two met for the first time at the International Physiological Congress held in Vienna. Here they planned an expedition to Pike's Peak, Colorado, to study the effects of high altitude and the factors involved in acclimatization, and this expedition was successfully undertaken in the following year. Thenceforward Henderson and Haldane maintained a close friendship, and Henderson's frequent visits to Europe brought him into contact with others, such as Barcroft of Cambridge and Krogh of Copenhagen, whose scientific interests were similar to his own.

The publication of Haldane and Priestley's classical paper in 1905 had already established the fundamental facts of the chemical regulation of the breathing, and had emphasized the physiological importance of carbon dioxide in this connexion. The significance of this work was fully appreciated by Henderson. It was indeed in harmony with his own work on the part played by carbon dioxide in the regulation of the circulation, and in a succession of papers he made a considerable contribution to the problem of the regulation of the acid-base equilibrium in the blood, with which respiration was closely connected. This in turn led him directly to a study of methods of resuscitation in cases when, for one reason or another, the

respiratory centre in the brain was showing signs of failure.

An outstanding instance of Henderson's shrewdness in the application of knowledge gained in the laboratory to the solution of practical problems in everyday life is afforded by his work on carbon monoxide poisoning. In severe cases of carbon monoxide poisoning, the best method hitherto advocated for treatment was by inhalation of oxygen; yet this was often disappointing since, as he showed, the respiratory centre had already begun to fail owing to the serious deficiency of oxygen to which it had been subjected because of the displacement of oxygen from the hæmoglobin in the blood by carbon monoxide. By adding 5 per cent or more of carbon dioxide to the oxygen inhaled, he found that the increased stimulus to the respiratory centre antagonized its failure, and with the maintenance of effective breathing the rate of elimination of carbon monoxide from the blood was greatly accelerated and a far better opportunity afforded for the eventual resuscitation of the victim. Oxygen – carbon dioxide inhalation is now universally recognized as the best treatment for carbon monoxide poisoning.

Henderson showed, too, that similar treatment might have a far wider application in clinical medicine when stimulation of the breathing or the maintenance of hyperpnœa might be requisite, for example, in the resuscitation of the new-born baby, in accelerating the elimination of volatile anæsthetics through the lungs after surgical operations, or in improving the breathing and reducing the risk of atelectasis in inflammation of the lungs. He had, however, an uphill fight before his views gained acceptance. Many regarded carbon dioxide as a poison the elimination of which from the lungs ought to be promoted and not hampered, and it took time to bring home the idea that carbon dioxide was also a natural stimulus to the breathing and could rightly be used for this purpose in clinical medicine.

Henderson's wide knowledge of the general physiology of respiration introduced him to many other practical problems. He was associated with the U.S. Bureau of Mines in the design of mine rescue apparatus and in the detailed investigation by which standards of ventilation were fixed for the ventilation of the Holland Tunnels between New York and New Jersey so as to prevent any risk of carbon monoxide poisoning caused by the heavy motor-car traffic. During the War of 1914–18, he worked on the physiological problems of aviation, and, after the start of gas warfare, on the properties of poisonous gases and means for securing protection against them; this led to the publication in 1927, in collaboration with H. W. Haggard, of his well-known book "Noxious Gases", a monograph which was to serve as the basis for the treatise "Schädliche Gase" by Flury and Zernik, which was published in 1931 in Berlin.

Much of Henderson's work is summarized in his book "Adventures in Respiration", published in 1938, and this affords an insight into the way in which his ideas developed and the difficulties that he faced and overcame.

A stout friend and a doughty opponent, Henderson retained throughout his working life the enthusiasm and the vigour of his youth. He had the courage of his convictions and really enjoyed a battle of words and wits, and he could speak bluntly in argument. But whether one agreed or disagreed with him, his views were always worthy of serious consideration. That he made mistakes is no doubt true, for no one is infallible; but there is no question that he played a great part in the development during the present century of our knowledge of the wide field of physiology embraced in the term 'respiration', and in the application of this knowledge to practical problems. It can rightly be claimed that his work on resuscitation has saved many lives that would otherwise have been lost. C. G. DOUGLAS.

Mr. H. H. Brindley

BY the death on February 18 of Harold Hulme Brindley, science lost a great personality. He was born at Highbury on June 17, 1865, the son of the then recorder of Hanley. Educated at Mill Hill School, he entered St. John's College, Cambridge, in 1884. Here he shared in all undergraduate activities, rowing in the boats, lieutenant in the Volunteers, president of the Debating Society, finally taking honours in the Natural Sciences Tripos in 1888. Careless of examinations, he obtained inspiration by aiding Weldon and Bateson in a period which was largely devoted to measurements designed to ascertain the technique of natural selection. An article on variation in the number of joints in the cockroach's tarsus greatly influenced Bateson, for it showed perfection with no intermediates whether there were four or five joints, each a 'normal' form, a 'discontinuous and total variation'. The facts were contested, as in regeneration a four-jointed tarsus is common, but he maintained his position, finding a case of four-jointed tarsi on all six legs. This led him later to a study of regeneration in general, especially in insects and vertebrates. His experiments on the different instars of Lepidoptera were particularly interesting.

Brindley then turned to the earwigs, with their long and short forceps. He scouted the idea that they were distinct species, a view extended to Xylotrupes beetles, two forms each with its fluctuations yet markedly discontinuous. For many years he kept cages of earwigs to experiment on their feeding habits and reactions. He found that their capture of insects by their forcipes in their nocturnal excursions was important, but they could live healthily on purely plant-food, though preferring dead animal matter. Dahlias and roses were mainly of use as hiding places, though their petals were agreeable. For their natural control, birds, except starlings, were unimportant. For proportions of sexes and other enumerations, he collected in the Scilly islands, but we recall with most interest his study of their parasitic infections. Clepsidrina abounded in the hind gut, while gordiid thread worms up to 50 mm. long often destroyed the whole gut; there were also acarine mites and fungoids, but parasitism did not produce any difference in respect to high and low males.

While collecting earwigs all over Cambridgeshire, Brindley also took the molluscs, obtaining more than a hundred species, and he observed that the progressive drainage of three centuries had not resulted in any marked invasion of Wicken Fen by terrestrial forms. Annual excursions to Arcachon were for the purpose of studying the larval processions of the moth, Cnethocampa, these first described by Réaumer. He broke up natural into artificial processions, but the question of direction is still undetermined. Mass attacks for oviposition were continuously made by tachinid flies, countered largely by the urticating properties of the larval hairs. During all these periods, indeed for fifty years, he had charge of the

first M.B. teaching in the Zoological Laboratory at Cambridge, more than five thousand students passing through his hands. He declined preferment, for the low pay of those days made private coaching necessary, while there were then no grants available for his research purposes. He became steward of his College during 1914–23, finally being elected a fellow in 1931.

Meantime Brindley had attained high distinction in other fields. He was a keen member of the Cambridge Cruising Club, and his knowledge of ships was unsurpassed. Hardy (later Sir William) had him and Graham Kerr as crew on his *Raven*, when she was the first yacht to pass westward through the Kiel Canal. He was one of the founders of the Society for Nautical Research in 1911, and he never missed a council meeting for twenty-eight years. He was a prolific writer in its journal, his chief subject the medieval ship. This and a love for St. Christopher led him to many ports and gave play to his artistic abilities, a study of medieval glass giving him great joy. He put his chief trust in engraved seals, and extended his research to every seaport in Europe. He arranged a special room for them in the National Maritime Museum at Greenwich, to which he gave his own unmatched collection. These settled the dates at which the rudder replaced the steering oar and the use of reef points. He was also an authority on primitive sailing craft.

Here was a character with a genius for friendship, equally at home in the discussions of art, literature and science, at first a noted contributor to the advance of biology, later a historian of nautical evolution, always the inimitable and humorous word-painter of the many noted personalities he had met, a real lover of life.

J. STANLEY GARDINER.

NEWS and VIEWS

Prof. A. R. Todd, F.R.S.

PROF. A. R. TODD has been appointed professor of organic chemistry in the University of Cambridge as from September 1944. Prof. Todd received his early education at Allan Glen's School, Glasgow, and passed from there to the University of Glasgow where, after a brilliant academic career, he graduated in 1928 and commenced his first research under the direction of Prof. T. S. Patterson. In October of the following year he went to work with Prof. W. Borsche in the University at Frankfurt-am-Main, where as a Carnegie Research Scholar he studied the chemistry of certain bile acids, and in 1931 presented the results of this work in the form of a thesis for which he was afterwards awarded the degree of Ph.D. On his return to England, he was elected to a Senior Studentship of the Exhibition of 1851 and worked for the next three years in the research laboratory of Sir Robert Robinson at Oxford. For his researches on the synthesis of anthocyanins during this period he was awarded the degree of Ph.D. At the invitation of the late Prof. G. Barger, he moved from Oxford to Edinburgh in 1934 to take up the study of the chemical constitution of vitamin B_1. The skill with which he led his team during this period and finally determined the structure of the vitamin, and of its fluorescent oxidation product, thiochrome, established his reputation as an outstanding organic chemist.

IN 1936 the Governing Body of the Lister Institute invited Dr. Todd to continue his researches in the Biochemical Department, and for the next two years he and his co-workers investigated the nature of the groupings responsible for the characteristic physiological action of vitamin B_1 and completed the synthesis of a number of compounds structurally related to the vitamin. Dr. Todd became a reader in biochemistry in the University of London in 1937. During his stay at the Lister Institute, he continued his researches on the constitution of the anti-sterility vitamin (vitamin E) and engaged in many other topics which included the chemistry of certain anthelmintic drugs and the active principles of *Cannabis indica*. In 1938 Dr. Todd was appointed professor of chemistry and director of the Chemical Laboratories in the University of Manchester, and with the increased facilities available at this famous centre of research, he was able to engage in an ever-widening array of synthetic and constitutional problems. Prof. Todd was elected a fellow of the Royal Society in 1942. Chemists and biochemists throughout the country will wish him every success and happiness in his new appointment.

Royal Commission on Population

IT is announced that the Royal Commission on Population has been constituted as follows: Lord Simon (*chairman*); Prof. A. M. Carr-Saunders, director of the London School of Economics; Sir Hubert Henderson, of the Treasury, formerly joint secretary to the Economic Advisory Council; Prof. A. W. M. Ellis, regius professor of medicine in the University of Oxford; Dr. Ethel Cassie, formerly senior assistant medical officer of health for maternity and child welfare, Birmingham; Lord Cranbrook, deputy regional commissioner for the Eastern Civil Defence Region; Lady Dollan, wife of a former Lord Provost of Glasgow; Mr. R. C. K. Ensor, research fellow of Corpus Christi College, Oxford; Mr. J. R. Hobhouse, of Messrs. Alfred Holt and Co., Ltd., Liverpool; Mrs. Margaret Jay, a member of the L.C.C.; Mrs. Gwen Longmoor, wife of a West Hartlepool factory worker; Mrs. G. P. Hopkin Morris, wife of the B.B.C. regional director for Wales; Lady Ogilvie, wife of the former director-general of the B.B.C.; Mrs. Helen Pawson, area representative for Wales of the W.V.S.; Mr. A. Roberts, general secretary of the Association of Card Blowing and Ring Room Operatives; and Mr. W. Dunkeld Robieson, editor of the *Glasgow Herald*.

Associated with the Royal Commission will be the three following technical committees: *Statistical Committee:* Prof. A. M. Carr Saunders (*chairman*), Mr. V. P. A. Derrick, Dr. D. V. Glass, Mr. R. R. Kuczynski, Mr. J. G. Kyd, Mr. H. Campion, Mr. A. Reeder, Dr. P. Stocks, Mr. F. A. A. Menzler and Mr. G. H. Maddex. *Economics Committee:* Sir Hubert Henderson (*chairman*), Mr. E. C. Ramsbotham, Prof. Alexander Gray, Prof. J. R. Hicks, Mr. W. B. Reddaway, and Mrs. Joan Robinson. *Biological and Medical Committee:* Prof. A. W. M. Ellis (*chairman*), Prof. E. D. Adrian, Prof. D. Baird, Dr. P. H. F. Bishop, Dr. C. P. Blacker, Mr. Eardley L. Holland, Dame Louise McIlroy, Dr. A. S. Parkes, Mr. E. W. Riches,

Sir Alexander Russell, Dr. P. Stocks and Dr. J. G. Thwaites. The secretary of the Royal Commission and of the three committees is Mr. N. F. McNicoll, of the Ministry of Health.

The terms of reference of the Royal Commission are to examine the facts relating to the present population trends in Great Britain; to investigate the causes of these trends and to consider their probable consequences; to consider what measures, if any, should be taken in the national interest to influence the future trend of population; and to make recommendations.

Lavoisier Statue in Paris

ACCORDING to the July 1943 issue of the French monthly philatelic review, *L'Echangiste Universel*, a copy of which has just reached Great Britain, a 4-franc postage stamp is being issued in commemoration of Lavoisier, the centenary of whose birth occurred on August 26, 1943 (see NATURE, Aug. 21, 1943, p. 207). Incidental reference is made to the removal "depuis un an" of the bronze statue of Lavoisier which stood at the north end of the Madeleine, not far from his town house (now rebuilt), 17 Boulevard de la Madeleine. *L'Echangiste Universel* appears to have no doubt about the fate of this superb monument—the work of Barrias—for its removal is attributed, with tactful obliquity, to the "service de la récupération des métaux", and the comment is added: "Pauvre Lavoisier connut à deux réprises, les vicissitudes de l'exécution capitale".

It will be remembered that Barrias adorned the pedestal of this beautiful work of art with two bronze reliefs, one of which depicted Lavoisier at work in his laboratory with Madame Lavoisier, his capable and devoted assistant, who is said to have learnt English so that she might translate for her husband the scientific papers of his great contemporaries, Cavendish and Priestley. In the other panel could be seen Lavoisier lecturing before the Paris Academy of Sciences, with Lagrange, Monge, Lamarck, Condorcet and Laplace among his audience. Though the pedestal was standing when *L'Echangiste Universel* recorded the destruction of the statue, the activities of the "service de la récupération des métaux" in occupied countries would seem to indicate that Barrias' bronze panels, with the statue, may never be seen again.

New Mathematical Tables

THE many users and admirers of the New York Work Projects Administration Mathematical Tables always studied the impressive list at the end of each volume of further tables to be published, and looked forward to the time when much-needed values would be available. It was a great shock to them when President Roosevelt announced, towards the end of 1942, that all W.P.A. activities were to cease; it was hard to realize that such a great international asset as the wonderful New York team of computers—the greatest the world has ever known—was to be destroyed at a time when its proved usefulness might have been diverted to the war effort. Actually, although the greater part has been disbanded, a nucleus has remained in being to help the Service departments, under the sponsorship of the U.S. Bureau of Standards. Naturally there were, early in 1943, a great number of tables ready for press, but not printed. It is with feelings of relief that we learn that the publication of these has now been provided for, and that four volumes have been announced already. The first gives reciprocals of the integers from 100,000 to 200,000, and thus extends the tables of Oakes (now unobtainable) and Cotsworth, which stop at 100,000. The second is a 10-place table of the Bessel functions $J_0(z)$ and $J_1(z)$ for complex arguments, giving real and imaginary parts for $\varphi=0(5°)90°$ and a range 0(0·01)10 of the modulus. The third table gives circular and hyperbolic tangents and cotangents to eight significant figures for $x=0(0\cdot0001)2$; it is thus a companion to the similar values of sines and cosines that appeared in 1939. The American practice of computing by calculating machines led to a revival some fifteen years ago of the Lagrangian interpolation formula. The new tables now provided give the coefficients for interpolating with any number of points (that is, tabular values) from 3 to 11. Incidentally, they include all the coefficients of Everett's central difference formula. The tables are to be issued by the Columbia Press, Ithaca, N.Y. (in Great Britain by Scientific Computing Service, Ltd., 23 Bedford Square, London, W.C.1).

British Medical Bulletin

IN 1940 the Medical Research Council, the Ministry of Information and the editorial department of the British Medical Association decided to send abroad abstracts of important articles in British medical journals, and Dr. Howard Jones was appointed to do this work under the direction of the editor of the *British Medical Journal*. By the end of 1941 a British Medical Information Service had been formed, and the British Council, which had supported the work from its inception, took it over as a permanent part of its work. The *British Medical Bulletin* is published in English, Turkish, Portuguese and Spanish, and Dr. Howard Jones, who is now a whole-time officer of the British Council, has made it a valuable addition to medical literature.

One Hundred Years at the Cincinnati Observatory

EVERETT L. YOWELL has an interesting article with the above title in *Sky and Telescope* (3, No. 2; December 1943). He gives an account of the development of the Observatory from the days when Ormsby MacKnight Mitchel resigned his professorship of mathematics, engineering and mechanics at Cincinnati College, and later, in the spring of 1842, started giving lectures on astronomy. These lectures were so well received that Mitchel announced his intention of building and equipping an observatory; and immediately he solicited membership for a society, each member to subscribe for a share at 25 dollars. It is remarkable that in spite of many initial difficulties—lack of funds in particular—Mitchel began the erection of the building with one carpenter and one mason as foremen, and on November 9, 1842, ex-President John Quincy Adams, then in his seventy-seventh year, laid the corner stone. In January 1845 the 11-inch refractor which Mitchel had purchased in Munich arrived; it was mounted in the spring of the same year.

As the Observatory was without endowment, Mitchel agreed to act as director for ten years without remuneration. Unfortunately, he had to devote a lot of time to lecturing at the College, which provided his only means of livelihood, and in consequence he

had very little time for astronomical work. The Observatory passed through many changes, including its removal to a better site and the appointment of Prof. Ormond Stone as director in 1875. He revived the study of double stars which had been undertaken by Mitchel, but was carried out in a desultory manner owing to other responsibilities. Stone was succeeded by H. C. Wilson (1882–84), Dr. Jermain G. Porter (1884–1930), E. L. Yowell, the author of the article (1930–40), and Dr. Elliott S. Smith, who succeeded him and is now in charge. A catalogue of stars observed by Dr. Smith is nearly ready for publication, and Dr. Paul Herget has done valuable work in computing orbits for the last two satellites of Jupiter.

Penicillin

A SPECIAL issue of the *British Medical Bulletin* (2, No. 1; 1944) devoted to work on penicillin contains special articles by Prof. L. P. Garrod, Prof. A. Fleming, Prof. H. W. Florey, Dr. E. Chain and Dr. M. E. Florey, and reviews of papers published between 1929 and 1943 on the discovery of penicillin and on its chemotherapeutic action, purification and chemical properties and on clinical trials of it. An appendix deals with the Oxford Unit, the slide-cell technique and communications not reviewed in this issue of the *Bulletin* or published in other countries. Everyone interested in penicillin will find this excellent review of the subject valuable.

West Indian Conference

THE first of a regular system of West Indian conferences is to be opened in Barbados on March 21 (see p. 320 of this issue). The conference, which will be presided over by Sir Frank Stockdale, British co-chairman of the Anglo-American Caribbean Commission, will consider means of raising the nutritional level in the Caribbean area, the re-absorption into civil life of persons engaged in war employment, the planning of public works for the improvement of agriculture, education, housing and public health, health protection and quarantine, industrial development, and the Caribbean Research Council and possibilities for its expansion.

Royal Society of Edinburgh : New Fellows

THE following have been elected ordinary fellows of the Royal Society of Edinburgh: Mr. John Anthony, lecturer in botany, University of Edinburgh; Dr. Daulatrai Bhatia, senior lecturer in zoology, Government College, Ludhiana, India; Prof. David Burns, Department of Physiology, University of Durham; Mr. John G. Carr, cancer research worker, Institute of Animal Genetics, University of Edinburgh; Dr. R. W. Craig, Scottish Secretary, British Medical Association; Dr. L. J. Davies, lecturer, Department of Medicine, University of Edinburgh; Prof. E. M. Dunlop, Department of Bacteriology, University of Durham; Mr. J. M. Geoghegan, president of the Society of Accountants in Edinburgh; The Hon. Lord Gibson, chairman of the Scottish Land Court; Mr. J. Methuen Graham, surgeon, Edinburgh Royal Infirmary; Prof. Arthur Holmes, Department of Geology and Mineralogy, University of Edinburgh; Dr. D. J. A. Kerr, lecturer on forensic medicine, School of Medicine of the Royal Colleges, Edinburgh; Prof. J. R. Learmonth, Department of Surgery, University of Edinburgh; Dr. W. Ledermann, assistant lecturer and Carnegie Fellow, University of St. Andrews; Dr. A. D. McEwen, chief bacteriologist, Moredun Institute Animal Diseases Research Association, Midlothian; Dr. Robert McWhirter, lecturer in radiology, University of Edinburgh; Major Noel Ewart Odell, Clare College, Cambridge; Dr. R. F. Ogilvie, lecturer in pathology, University of Edinburgh; Prof. G. D. Preston, Department of Physics, University College, Dundee; Mr. W. S. Procter, regional engineer, Post Office Engineering Branch, Scottish Region; Dr. T. Robertson, district geologist, H.M. Geological Survey, Edinburgh; Dr. R. W. Scarff, reader in morbid anatomy, University of London; Mr. E. Openshaw Taylor, lecturer in electrical power and machinery, Heriot-Watt College, Edinburgh; Dr. O. A. Trowell, lecturer in human physiology, University of Edinburgh; Prof. J. Stirling Young, Department of Pathology, University of Aberdeen.

Announcements

THE triennial award of the Coopers Hill War Memorial Prize and Medal, which fell in 1943 to the Institution of Electrical Engineers, has been made by the Council to Mr. Harold Page, for his paper on "The Measured Performance of Horizontal Dipole Transmitting Arrays".

THE award for 1943 of the Page Prize for the best thesis submitted in lieu of the Associate Membership Examination of the Institution of Electrical Engineers has been made by the Council to Mr. J. V. Beaumont for his thesis entitled "Types of Power Transformers, with special reference to On-Load Voltage Regulators".

THE Institution of Electrical Engineers will this year make awards of the Duddell and Manville Scholarships. These Scholarships are each worth £150 a year for three years. They are open to British subjects who are less than nineteen years of age on July 1, 1944, who have passed the matriculation examination of a British university, or an equivalent examination, and who wish to take a whole-time day course in electrical engineering. Applications for particulars and nomination forms should be addressed to the Secretary of The Institution, Savoy Place, London, W.C.2. Nomination forms must be returned not later than April 15.

THE ninth Pedler Lecture of the Chemical Society will be delivered by Dr. C. R. Harington on March 16 at 2.30 p.m. Dr. Harington will speak on "Newer Knowledge of the Biochemistry of the Thyroid Gland".

A WEEK-END course for medical practitioners on factory medical services and industrial diseases will be held at the London School of Hygiene and Tropical Medicine on March 25–26. It will be opened by Sir Wilson Jameson, chief medical officer of the Ministry of Health, and lectures will be given on "Tuberculosis and the Industrial Worker", "Industrial Diseases of Coal Miners", "Medical Inspection of Canteens", "Young Persons in Industry", and "The Medical Selection of Factory Personnel". The fee of one guinea for the course should be sent to the Secretary, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1, not later than Monday, March 20.

LETTERS TO THE EDITORS

Mechanism of Formation of the Fertilization Membrane in the Sea Urchin Egg

THE mechanism of formation of the fertilization membrane in the sea urchin egg has long been a matter of discussion. Runnström, Monné and Broman[1] recently reviewed the essential points in this discussion. They also resumed, on the eggs of *Psammechinus miliaris* and *Echinocardium cordatum*, the study of the birefringence of the membrane first described by Runnström[2].

The membrane presents a double refraction which is negative in the radial direction. No similar birefringence could be observed on the surface of the unfertilized egg. During the elevation of the membrane the birefringence increases until it reaches the normal value (retardation M 12 mμ).

Unfertilized eggs transferred to hypertonic solution (2 ml. sea water + 0·6 ml. 2·5 N sodium chloride) sometimes form a membrane which is more or less granular and the birefringence of which is considerably lower than that of the normal fertilization membranes. The granules in question seem to be identical with the 'cortical granules' of the unfertilized eggs. These granules are formed at the maturation of the egg. They disappear at fertilization, as was observed by Hendee[3], Lindahl[4] and Moser[5]. The cortical granules are easily observed in sections of unfertilized mature eggs fixed with Fleming's solution and stained with hæmatoxylin.

The sperm of sea urchin was frozen, dried *in vacuo* and extracted with methanol. The residue was treated with sea-water at 90° for three minutes. The extract thus obtained[6] (containing 0·5–0·7 mgm. N per ml.) interferes even in considerable dilutions (1 : 200–1 : 300) with the normal membrane formation, without inhibiting the entrance of the sperm and the copulation of the pro-nuclei. The division of the nuclei always proceeds, while the segmentation of the cytoplasm is more or less inhibited.

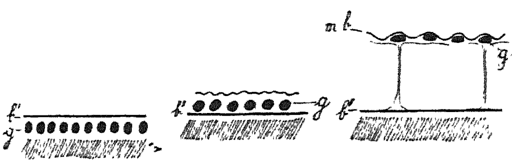
The inhibition of membrane formation occurs in many different degrees (1–4) according to the concentration of the sperm extract. (1) No membrane separates from the egg surface. Even when the eggs are transferred to a hypertonic solution, no membrane becomes visible. Occasionally, however, an elevation of a thin membrane occurs, which is localized at a part of the egg surface.

(2) A membrane is formed, but the perivitelline space of the egg surface is very narrow. In a hypertonic solution, the membrane is seen to be fully separated from the egg surface. The membrane of these eggs is granular and its double refraction is rather low, the retardation amounting only to about half the normal value. Eggs of this kind have been fixed and stained. In eggs with granular membranes no cortical granules are present. The granules of the membrane, however, are stained in the same way as the granules present in the surface of the unfertilized eggs.

(3) The perivitelline space has the normal width. The membrane is somewhat folded or curled, but no granules are visible. The double refraction is not different from that of a normal, smooth membrane. Intermediate stages between (2) and (3) are observed. In these, one part of the membrane may be granular, another part curled, without visible granules. The granules evidently elongate in a tangential direction and enter as an element of the membrane. *The double refraction of the fertilization membrane reaches its normal value only when the granules have been incorporated with the membrane.*

(4) In most diluted solutions of sperm extract a normally raised, smooth membrane may appear. Intermediates exist, however, in which one part of the membrane is curled or even granular, the other being smooth and of perfectly normal appearance.

It seems reasonable to assume that the observations described above under (1)–(4) represent different stages in the normal formation of the fertilization membrane. This view is strongly supported by observations on unfertilized eggs of *Echinocardium cordatum*, which have been transferred to a mixture of 7 parts sea-water and 1 part rabbit or sheep serum. In this mixture perfectly smooth membranes are formed, but the process gradually passes through the four stages described above. Only after about fifteen minutes from the beginning of the process are the normal smooth membranes formed.



(1) (2) (3)

These and a number of further observations give a fairly precise picture of the formation of the fertilization membrane. The first step of the membrane formation may be illustrated by the accompanying schematic diagrams. In (1), representing the conditions before the activation, the cortical granules (g) are situated below the limiting border (b') of the egg. This border is characterized optically by its refringence. With dark-ground illumination, the border is seen to have a yellow-orange colour. The activation involves a reorganization of the peripheral part of the cortex. The border retracts, leaving outside itself a rim of hyaline substance in which the radially, somewhat elongated, cortical granules are found (cf. 2). Simultaneously with this retraction the orange colour of the border changes to a bluish-white, as observed with dark-ground illumination[1,2]. The state represented by (2) could be well recognized in Echinocardium eggs. The rim still adheres to the limiting border (b'') and is not separated from this when the eggs are immersed in hypertonic sea-water.

At fertilization, the retraction starts from the entrance point of the sperm cell and thence spreads over the egg surface in a wave-like manner, as described by Just[7]. About ten minutes after fertilization, the hyaline layer becomes visible on the surface of the normal egg. It is obvious that the formation of the hyaline rim of (2) and that of the hyaline layer are quite analogous processes, the mechanism of which may also be similar.

The step following that of (2) is represented by (3). The membrane is delaminated from the surface border of the cortex and raised under the action of osmotic forces. In the eggs of Echinocardium submitted to treatment with sea-water – serum mixture, even the raised membrane very often still adheres to the border of the cortex by means of more or less developed strands which may later disintegrate.

Such strands are schematically represented in (3). The further development of the granular membrane needs no comment in addition to the above description.

The so-called vitelline membrane of the unfertilized egg is not identical, as often assumed, with the fertilization membrane. It forms only a part of the latter. In certain circumstances, the cortical granules are not incorporated into the membrane. Under these conditions, a thin membrane results which has a low double refraction and may be identical with the vitelline membrane.

The description given above of the fate of the cortical granules is at variance with the ideas entertained by Moser[5] concerning their role in the activation.

Water Contents of Last-stage Larvæ, Pupæ, and Adults of the Meal Moth

ACCORDING to Speicher[1], larvæ and pupæ of the meal moth, *Ephestia kuehniella* Zeller, an important pest in meal stores, maintain a constant percentage of free water, independent of the relative humidity of the environment.

In contrast to Speicher's results, our observations show that migrating larvæ of Ephestia, which have been reared at low relative humidities, have a much lower average water content than larvæ kept at high humidities, although the water contents show considerable fluctuation.

On the other hand, water contents of pupæ of all ages show a practically steady average figure, which is independent of the relative humidity in which the insects were reared. This figure (see accompanying table), which agrees very well with Speicher's value, lies between the average percentage water contents of larvæ reared at 30 per cent and 70 per cent relative humidity respectively.

	Average water content as % of body weight	
	30% relative humidity	70% relative humidity
Migrating larvæ	57·3	73·5
Pupæ	65·4	66·4
Adults	65·4	66·3

The average water content of adults is practically the same as that of pupæ, and again appears to be independent of the humidity of the environment.

It is generally held that the water content in various instars of insect development can be regulated by the retention of metabolic water[2]. It seems, however, that Ephestia larvæ cannot compensate entirely for the increased rate of evaporation of water at low relative humidities.

When larvæ reared at low relative humidities are preparing to pupate, a more efficient mechanism of regulation comes into operation, so that the water contents of the resulting pupæ are almost identical with those reared at high humidities. The average weight of these pupæ developing at low humidities (30 per cent relative humidity), however, is approximately only 80 per cent of those reared under standard conditions (70 per cent relative humidity). It may be that the regulatory process involves the oxidation of a greater weight of reserve substances during the prepupal stage of those individuals reared in the drier environment.

Low environmental humidity definitely increases the duration of larval development (fifty days at 30 per cent relative humidity, as compared with thirty-three days at 70 per cent relative humidity), but the length of the pupal instar is only slightly affected.

New Interference Phenomena with Newton's Rings

SOME striking new interference phenomena have been found with Newton's rings by using multiple-beam interference instead of the usual two beams. The rings, formed between a convex lens and a flat piece of glass, are modified profoundly by the employment of multiple beams. The two surfaces in contact are coated (by evaporation *in vacuo*) with high reflecting coefficient transparent silverings, the reflecting coefficient exceeding 0·85 for the green mercury line. The resulting multiple beams lead to the production of fringes which are characterized by their remarkable sharpness. The fringes in transmission are fine narrow brilliant rings on a broad dark background, and in reflexion can be seen a complementary system of fine dark 'absorption' fringes on a broad bright background.

Normal Incidence. Typical transmission rings (green mercury) with light incident normally on the interference faces are shown in Fig. 1. The sharpness is unique. It is necessary to restrict the incident light to a single angle of incidence by employing a small source at the focus of a lens in order to achieve the best definition. Comparison with the ordinary classical two-beam rings reveals the superiority of the multiple-beam fringes in the following particulars:

(1) They are much more intense.

(2) They are so sharp that very high precision can be attained. A change of 1/100 of an order can readily be *accurately* measured. This corresponds to a displacement of only 25 angstroms between the optical components. A great increase in precision is thus now available in all the numerous metrological applications of Newton's rings.

(3) The fringes are so inherently sharp that fine-scale surface defects and irregularities on the glass surfaces are rendered as detail in the fringes. For the reproduction shown as Fig. 1, the flat component was a simple piece of glass, and all the local

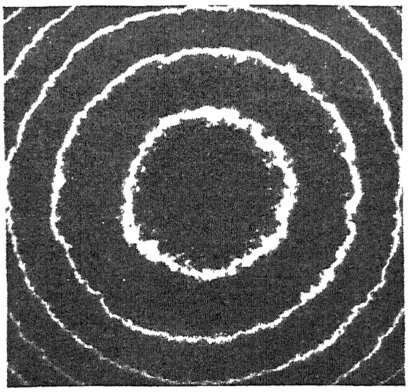

Fig. 1. Newton's rings with multiple beam interference.

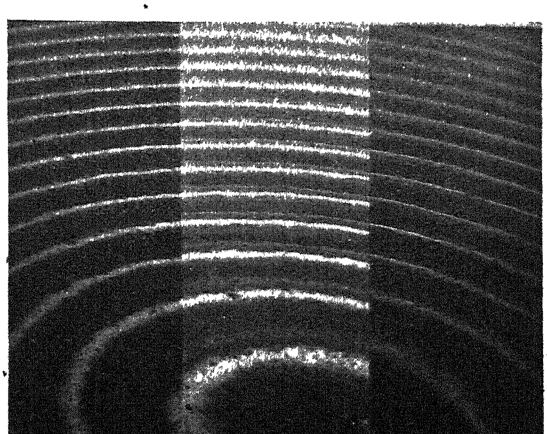
irregularities are clearly shown by the irregularities of fringes.

(4) By matching the curved component against a high-grade optical flat, the perfection of figure of the lens surface is revealed, with very great sensitivity. This effectively extends to curved surfaces the existing multiple-beam Fizeau test, used to-day only for flat surfaces.

Non-normal Incidence. New interference phenomena appear when the angle of incidence is other than normal. The fringes are no longer located in the film but lie on focal curves, one half of the ring system being situated before and the other half behind the interference film.

The fringes become double; the separation between the two components growing steadily with increasing incidence. One component moves *out* towards the next higher order, becoming progressively *weaker* and also *sharper*. These two components are plane polarized, mutually perpendicularly. The phenomena are shown clearly by Fig. 2, which refers to an incidence of 60°. Fig. 2*b* shows the doubling, with no Nicol prism in the beam. In Fig. 2*a* a Nicol has been interposed to pass the beam with the magnetic vector perpendicular to the plane of incidence; and in Fig. 2*c* the Nicol has been set to pass the parallel component. Owing to the peculiar focal properties of the non-normal fringes, only the fifth and sixth fringes are in focus in this reproduction.



a b c

Fig. 2. Doubling due to differential phase change at reflexion. (*a*) Magnetic vector perpendicular to plane of incidence; (*b*) no Nicol prism; (*c*) magnetic vector parallel to plane of incidence.

The cause of the doubling is the existence of a differential phase change at reflexion at the silver surfaces. The phase change is different for the mutually perpendicular directions of vibration of the light. This differential effect has been measured over the range of incidence 0–80°. To the first order, the observations closely confirm the predictions of classical electromagnetic theory. Up to an incidence of 60° the experimental curve runs closely parallel to the theoretical curve, but is displaced upwards by a quite small, but real, amount, 0·007 λ. The observations reveal a marked, but small, inflexion at 63°, not predicted by theory, which is probably incomplete as to finer detail.

The remarkable sharpness of the parallel vector (see fifth and sixth fringes) is due to the higher effective Fresnel reflecting coefficient for this vector. It can be demonstrated that this parallel vector is rapidly absorbed with increasing incidence, and the rate has been determined. It follows from this that an evaporated silver film, when used to transmit light incident at high angles of incidence, should act as a polarizer (partial) in a manner similar to that which makes tourmaline act as a polarizer by differential absorption. This interesting property has been shown to exist, and can be very easily demonstrated.

The same characteristic fringe-doubling due to the differential phase change at reflexion at the silver has been found with small-gap Fabry-Perot interferometers, with the necessary modification that the parallel vector moves *inwards*, to the region of higher order of interference. For gaps of less than 1 mm., the differential doubling can lead to an appreciable loss in resolution, if the incident light is not polarized to compensate for this.

Full experimental details, together with an analysis of the phenomena very briefly surveyed here, have been communicated elsewhere.

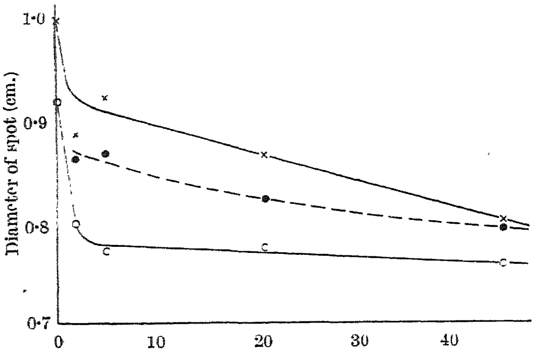
Influence of an Adsorbed (Inner) Layer on the Cohesion of a Solid

In Nature of January 22, Benedicks and Sederholm, under the above title, showed that the exposure to air of freshly cut surfaces of paraffin, lead and tin resulted in a lessened cohesion when two plane surfaces of the solid in question are brought into contact. By measuring the cohesion after different periods of exposure to the air, it was shown that, in the case of tin for example, important changes took place during the first five minutes exposure of a freshly cut surface. These changes are attributed to the rapid formation of a thin adsorbed layer.

A similar effect has been observed with silver and with iron by another simple technique. When a drop of distilled water of volume 0·03 c.c. is allowed to fall a distance of 2 cm. from the jet of a burette on to a freshly cut surface of the metal fixed in a horizontal position, the diameter to which the drop spreads before coming to rest is governed to a certain extent by the length of time the metal surface has been exposed to air.



Curve I, ×; Curve II, ●; Curve III, ○.

The effect of exposing freshly cut silver (Curve III) and freshly cut iron (Curve I) to air inside a desiccator containing calcium chloride is illustrated in the accompanying graph, which also shows (Curve II) that the air of the laboratory in which these experiments were carried out does not affect the freshly cut silver in the same manner as does the drier and purer air inside the desiccator. In these experiments the surfaces were freshly cut by means of the unused emery face of a piece of Hubert emery paper grade 1*M*, any residual emery powder being quickly rubbed off by a few strokes with a ball of dry cotton-wool.

The importance of the pre-exposure of a metal surface to air in connexion with its chemical behaviour was established some years ago by U. R. Evans[1].

Determination of Specific Heat of Metals

I HAVE recently discovered a simple and novel method for measuring the specific heat of metals having known temperature-resistance coefficients.

A current, of sufficient magnitude to heat a wire to its melting temperature in a short time (within, say, 5×10^{-2} sec.), is passed through the wire. Under these conditions, the losses from the wire are negligible. By recording oscillographically the current through, and potential across, the wire, one can determine at any instant the resistance of the wire, from which its temperature can be found, and the energy imparted to it. From a single test one can thus draw a curve connecting energy input with temperature rise, from which one can determine the specific heat at any temperature within the range of the test or the mean specific heat over any range of temperature.

Fuller details, together with test results, will be given in an E.R.A. report shortly.

The method might be applied to any electrical conductor the resistance of which varies with temperature, the temperature coefficient being known.

Dipole Moments of Polyatomic Molecules

IN calculating the dipole moments of polyatomic molecules, it is assumed that the observed moment is vectorially composed of the moments of the various links or bonds. The bond moments so deduced have no simple relationship to the values calculated from the internuclear distances and the electronic charge. The valency angles calculated from them vary and do not agree with theoretical values or even those found by other methods; interactions of the bond moments have been postulated in order to produce agreement between the calculated and the observed values. There is no vector between the bonds connected by single links due to free rotation or uncoupling.

These and other difficulties in the interpretation of dipole moments of polyatomic compounds are simplified by the conception that the dipole action is due to the rotation of the needle-shaped dipole[1], and each bond affects the polarization with the components of the other bonds calculated along the connecting links. The moments of the bonds are uncoupled when connected by single links. In the case of rigid molecules, the bond moments are affected inductively by the components along the connecting links and then add up vectorially.

Thus, according to vectorial addition, the observed moment in a triatomic molecule *ABA* is (I) $R = m^2 + m^2 + 2mm \cos \theta$, where m is the *AB* bond moment and θ is the *ABA* angle and the molecule is polarized along *BR*, where the angle *ABR* is $\theta/2$. According to the new law, (II) $R = m + m \cos \theta$, and the direction is along each *BA*.

When the dipoles are separated by a single connecting link with the same angle, the observed moment according to the new law is (III) $R = m + m \cos \theta^2$. If one more additional link making the same angle is introduced, the resultant is $m + m \cos \theta^3$. If the link bonds have their own moments, the respective components have to be added, paying regard to the sign. When the two end bonds are dissimilar, the resultant is represented by the arithmetic mean of the values calculated in the direction of each bond, or by the rule of squares.

In water the bond moment OH is $\frac{1}{2}$ ionic or dipolar ($2 \cdot 5D$), which, using 105° as HOH angle, gives $1 \cdot 88$ as the dipole moment of the H_2O molecule (obs. $1 \cdot 87D$). The calculated value for hydrogen peroxide assuming the tetrahedral angle for H–O–O is $2 \cdot 22D$ (obs. 2·14). The C–O bond is $\frac{1}{2}$ ionic ($3 \cdot 5D$) in alcohols and acids and $\frac{1}{4}$ ionic ($1 \cdot 75D$) in ethers, which leads to $1 \cdot 68D$ for the dipole moment of all alcohols and 1·13 for all ethers. The dipole moments of substituted anisoles are also in full agreement with the calculated values. The C=O bond is $\frac{1}{2}$ ionic and the calculated bond moment 2·98 is observed in all ketones. The calculated dipole moment of acetic acid is $1 \cdot 76D$ (obs. $1 \cdot 71D$). The uncoupling of C=O and OH bonds takes place owing to free rotation along the link C–O. The dipole moment of ethylene dichloride is $1 \cdot 69 \times (1 - \cos \theta^2) = 1 \cdot 50D$ (obs. $1 \cdot 5D$ at 200°); of quinol dimethyl ether using COC angle 105°, found in dimethylether, is $1 \cdot 75 (1 - \cos 75^{\circ 2}) = 1 \cdot 64D$ (obs. $1 \cdot 67D$).

The law of component moments accounts quantitatively for the anomaly of flexible molecules, the ortho, meta, para moments in aromatic compounds, the substituted anisoles, the diphenyls and naphthalenes, etc., on the basis of the regular geometry of the

molecules and theoretical values of angles and bond moments. Details will be published elsewhere.

Solubilization of Dyes in Non-aqueous Solvents

THOUGH a large number of instances of solubilization of water-insoluble substances like dyes, hydrocarbons, etc., in aqueous solutions of detergents are known[1], very few definite cases of the same phenomena have been reported for non-aqueous systems. In a recent note, McBain[2], for the first time, has adduced qualitative evidence to show the existence of such solubilization by hydrocarbon-soluble soaps and detergents, and has very recently cited a few more instances[3].

I have, however, observed that such solubilization is of rather frequent occurrence in the behaviour of resins dissolved in non-aqueous solvents. A systematic study has been undertaken and the results will be reported later. The present note records the hitherto unnoticed strong solubilizing power of resins, and also to direct attention to some peculiarities in this process not noticed by McBain and co-workers[2]. Their "experimental procedure has been to take approximately 1% solutions of pure or commercial detergents as supplied by the makers and add solid dye. Solubilization is indicated by the almost immediate coloration of the liquid." There is, however, an underlying source of error in this process of indicating solubilization, owing to the fact that some dyes ordinarily regarded as insoluble dissolve in traces in hydrocarbons to give a colourless solution which develops colour in presence of the dissolved resin (solubilizer). A good example is rhodamine; this dissolves slightly in benzene or toluene to give a colourless solution, which becomes pink on dissolving even a fraction of one per cent resin in it. So it is always necessary to check against such 'false' solubilization by noting the effect of adding the solubilizer to the dye-saturated solvent. This and other peculiar cases of chromatic interactions between dyes and resins have been observed and are receiving closer study.

A few cases of true solubilization are now being reported. The resins used have been crystalline abietic acid (the chief constituent of American rosin), purified glycerol triabietate (the chief constituent of ester gum) and soft resin of shellac, in 0·5 per cent solution in toluene and benzene at room temperature. Increase of temperature has always been found to favour solubilization. So far, about fifty pure and commercial dyes have been tried, of which only about ten have shown true solubilization to a more or less extent as given in the following list, cases marked with an asterisk indicating a very strong effect: Ester gum solubilizes methyl violet*, phenoplastic blue *RB**, methylene blue, brilliant green, alkali blue, quinoline *A*, safranine, neutral violet and phenoplastic yellow *6G*; abietic acid solubilizes monalite red *2RS*, brilliant green, alkali blue and quinoline *A*; soft resin of shellac solubilizes methyl violet*, phenoplastic blue *RB** and brilliant green.

McBain[2] believes that non-aqueous solubilization, like its aqueous counterpart, is due to adsorption of the dyes on the micelles. We, however, find in this phenomena a manifestation of the already observed liquid-like behaviour of resins[4], which might perhaps be ultimately due to the strong association tendency of the resin molecules, leading to formation of association dimers and polymers with the dye molecules.

A detailed examination of the mechanism of the process is, however, postponed until more data are forthcoming.

Reported Asymmetric Synthesis of Santonin

SOME time ago[1] Paranjape, Phalnikar, Bhide and Nargund reported a synthesis of santonin from optically inactive materials: they now[2] claim that their product was active, being almost entirely the natural (*l*-) isomer. They state that the activity originated in the methylation of a 2-formyl*cyclo*hexanone derivative, and that the crude methylation product from 2-formyl*cyclo*hexanone (I) itself had the large specific rotation of $-26 \cdot 2°$ in chloroform. Although they did not isolate 2-methyl-2-formyl*cyclo*hexanone (II), they claim that an optically active derivative was prepared in a state of purity.

Such an asymmetric synthesis from inactive materials violates no fundamental law and might theoretically be expected to occur once in about $(10^{10})^{20}$ trials.

Nevertheless, Paranjape *et al.* claim to have achieved the asymmetric synthesis repeatedly. As we were interested in the products for another reason, it seemed worth while to repeat one of these experiments.

Sen and Mondal[3] prepared (II), though not in a pure condition, and established its structure by hydrolysis to 2-methyl*cyclo*hexanone. We find that (II) may readily be purified by fractionation at low pressure, forming a colourless oil of camphoraceous odour, b.p. 47°/0·05 mm., n_D^{18} 1·4683 (Found: C, 68·2, 68·4; H, 8·6, 8·4. $C_8H_{12}O_2$ requires C, 68·6; H, 8·6 per cent); the hydrolysis to methyl*cyclo*hexanone was confirmed. Neither the crude methylation product from (I) nor pure (II) showed any optical activity whatsoever.

RESEARCH ITEMS

Duration of Immunization against Diphtheria

H. Lyndhurst Duke and W. B. Stott (*Brit. Med. J.*, 710; Dec. 4, 1943) have published a paper of interest to all who have followed the Ministry of Health's advice that children—and especially children under five—should be immunized against diphtheria. They have studied the duration of artificial immunity to diphtheria in the Cuckfield and Burgess Hill areas, which have a child population of 9,600 children aged 1–15 years, 95 per cent of whom have been immunized as a result of a campaign started in 1936 by Dr. Stott. A large number of children under five were immunized. Material was therefore available for the study of the duration of the immunity, and more than 3,000 children were tested by the Schick test 2–6 years after immunization. The authors found that the number of children who lost their immunity rose steadily as time went on; after two years 4 per cent, and after six years 18 per cent had lost it. They conclude that it is important to test children some two years after the completion of the immunization. Boys and girls differ little in their response to the antigen. In great cities some 50–70 per cent of children may become naturally negative to the Schick test, but in rural areas natural Schick-negatives may be few, and in the area studied there was no evidence among children under five that such natural immunization had developed. Discussing the question of diphtheria carriers, the authors state their view that, year by year, as the campaign for immunization against diphtheria goes on, a large body of potential carriers is being formed, and that this has probably already built up the natural or artificially acquired level of immunity and acts as a buffer against large-scale introduction of new sources of the infection. It is important to remember that artificial immunization protects against the toxin which causes the symptoms, but not against the bacillus.

Gut of Nebaliacea

A COMPARISON of the structure of the gut of three species of the Nebaliacea, *Nebalia bipes* (Fabricius), *Nebaliella extrema* (f. Thiele) and *Nebaliopsis typica* (Sars) brings out some significant facts. Miss H. G. Q. Rowett (Discovery Reports, 23, 1–18; Cambridge: at the University Press, 1943; 3*s*. net) has subjected these to a searching inquiry and shows how well adapted each one is to its mode of feeding. Nebaliella and Nebaliopsis were obtained from the "Discovery" collections and are compared with *Nebalia bipes* from British shores. *Nebalia bipes*, the common British shore-living species, has been studied alive as well as in sections. It is a filter feeder, as Cannon (1927) has already shown. Its feeding mechanisms enable it to deal with larger particles as well as with the usual incoming flow of small matter in the zone. While *Nebalia bipes* lives usually above the mud just beneath or among pieces of seaweed, shells and stones, *Nebaliella extrema*, also a mud-dweller, is more a true burrower and feeds indiscriminately on the mud. Owing to the lower value of the food, the gut is adapted to deal more rapidly with much food. *Nebaliopsis typica* is specially interesting, for its gut is much specialized. Living at great depths in the open ocean, its surroundings are very different from the other species studied. There is good reason to believe that it feeds on eggs. A large digestive sac has been developed as a store chamber, meals probably fluctuating in abundance, and the lumen of the intestine has been reduced to ensure that nothing escapes thorough digestion. The fore gut is adapted to the puncturing and sucking of the eggs, and the mandibles to holding them in position during these processes. In this connexion it is interesting that the adaptations of the gut are very similar to those of the nudibranch *Calma glaucoides* of British coasts, which feeds on the eggs and embryos of small shore fishes. Special attention has been given to the musculature of the gut in all three forms. The plan is simple and constant, the changes being chiefly associated with the structure of the chitinous parts, and these in turn may be correlated with the habits of the species. The work is carefully illustrated with well executed text-figures.

Classification of Lamellibranchiata

BASED on a study of the ciliary mechanisms of the gills of the Lamellibranchiata, Daphne Atkins proposed a classification of the group. One of the divisions was termed the Microciliobranchia, and the author has now continued her investigations into the musculature of the gills of this section of the Lamellibranchs (*Quart. J. Micro. Sci.*, 84; 1943). The gill muscles serve several purposes; slight contraction removes obnoxious particles and opens and closes the grooves; more violent contraction not only reduces the size of the gills but also obliterates the interfilamentar and interlamellar spaces, and so reduces the possibility of injury to these delicate structures when the valves are violently closed. The major muscles of the gill axes are arranged in two groups, longitudinal and transverse. The former are in two sets, but as both are inserted into the shell they are able to act as retractors of the gills. The transverse muscles are also in two sets, one above and one below the chitinous support above the axial food groove, and by their action separate or bring together the demibranchs. In addition to these axial muscles there are also series in the demibranchs themselves.

Photoperiodism in the Potato

THE Imperial Bureau of Plant Breeding and Genetics at Cambridge has recently issued a technical communication by C. M. Driver and J. G. Hawkes on "Photoperiodism in the Potato" (Pp. 36. 2*s*. 6*d*.). In Part 1 of the bulletin, C. M. Driver reviews the experimental methods of a number of workers since Garner and Allard's classical investigations in 1920. A discussion then follows on the effect of long- and short-day periods upon vegetative growth, flowering and seed production, stolon and tuber formation and maturity. Potatoes differ in their response to day-length and it is evidently an inherited factor. Some South American species do not form tubers under long-day conditions, while others form them equally well under a range of photoperiods. Temperature has a modifying effect upon the response of the plants to length of day, a high temperature generally being antagonistic to tuber production, while a very low temperature may encourage varieties to form tubers under longer photoperiods than usual. Part 2, by J. G. Hawkes, describes experimental work carried out at Cambridge on the reaction to long and short days of a number of South American potatoes obtained from the Empire Collection. Some 75 clones from eight species were tested and assessed on tuber weight, tuber number, stolon production, time of maturing, height of plants, and flowering. It seems

that flowering in the potato may be dependent on the quantity of light received rather than on the actual length of day, and it is tentatively suggested that the photoperiodic mechanism may apply only to the dominant method of reproduction—in this case, to tuber formation.

Inheritance of a Mutation in Wheat Rust

T. Johnson and Margaret Newton have described the mode of inheritance of a mutant in *Puccinia graminis Tritici* Eriks. and Henn. (*Canad. J. Res.*, 21, C 205; 1943). The mutant is characterized by the production of white pustules on barberry owing to marked destruction of the chlorophyll in the infected area. The inheritance of this is independent of sex or physiological race. The original isolate produced approximately equal numbers of white and normal pustules, and crosses with other races showed that diploidization of the mycelium of normal pustules with spermatia from white pustules initiated races that also produced approximately equal numbers of white and normal pustules. Normal × normal crosses produced normal pustules, whereas white × white were sterile. Uredospores arose only occasionally in white pustules and then by diploidization by spermatia or mycelium from normal pustules.

Meiosis in the Striped Hamster

G. PONTECORVO (*Proc. Roy. Soc. Edin.*, 62, 32; 1943) has compared the meiotic behaviour of the striped hamster with that of the golden hamster previously examined by Koller. The striped hamster has $2n = 24$ chromosomes, a remarkably low number among Mammalia. During mitosis the heteromorphic sex chromosome pair can be distinguished easily since the differential segment is apparent; in the golden hamster, that cannot be found during mitosis. During mitosis, nucleoli are to be found in the striped hamster, but the golden hamster has none. These and other facts suggest that the nucleic acid metabolism is lower in the golden than in the striped hamster. The author makes the interesting suggestion that euchromatin and heterochromatin are similar in containing genes, but that the genes of the euchromatin are specifically distinct from one another and therefore metabolize nucleic acid at different rates. The heterochromatin, on the other hand, contains genes which are closely similar to one another or even replications. One block of heterochromatin may contain different genes from any other block. Hence the nucleic acid cycle is specific for this block. Further, the absence of many sex-linked genes in Mammalia, ever-sporting characters in Drosophila, the rarity of recognizable genes in heterochromatin in an evolution of the sex chromosome, could all be related to this hypothesis.

Transmission-Line Problems and the Impedance Circle Diagram

Willis Jackson and L. G. H. Huxley, in a paper read recently in London before the Institution of Electrical Engineers, point out that in modern micro-wave technique, transmission lines find wide application both for the interconnexion of component pieces of equipment, such as oscillators and receivers and aerial systems, and as inductive and capacitive circuit elements within these pieces of equipment. In the former they are normally several wave-lengths long, but in the latter only fractions of a wave-length. The analysis of their behaviour has been greatly facilitated by the development of a circle diagram technique, the theory and application of which are discussed. This is followed by a discussion of the fundamental principles underlying the transmission-line equations on which this technique is based, and of the meaning to be attached to the word 'impedance' at very high frequencies in respect of terminating attachments to lengths of transmission line. In particular, attention is given to the physical possibility of producing a non-reflecting termination, on one aspect of which there appears to have been widespread misunderstanding.

Variation of Latitude at Greenwich, 1936–40

SIR HAROLD S. JONES, the Astronomer Royal, has communicated a paper (*Mon. Not. Roy. Astro. Soc.*, 103, 5; 1943) on this subject, which discusses the results obtained with the Cookson floating zenith telescope, Royal Observatory, Greenwich, since the introduction of the new programme in 1936. In that year the instrument was moved from the courtyard of the Royal Observatory to the Christie Enclosure, and the new programme consisted of twenty-four groups of pairs of stars, each group extending over about one hour of R.A. Three groups are observed nightly, centred at Greenwich mean midnight, and hence each group can be directly connected with groups on either side of it, differing by 2^h R.A. at the most. Observations were interrupted in the autumn of 1940, and in addition, slight damage to the instrument necessitated dismantling and storing the objective and telescope. The available material up to the autumn of 1940 has been used to determine the variation of latitude over the four years 1936–40. The group corrections, to be added to observed-tabular Z.D. north, are given, and these are in close agreement with those derived by Hulme for the years 1936–38. They contain the periodic term in R.A. $+ 0{\cdot}118'' \sin \alpha + 0{\cdot}012'' \cos \alpha$. Values of the latitude variation, applicable to N.P.D.s, are given for each of the years 1936–40 inclusive.

Interstellar Calcium Clouds

REMARKABLE spectrograms showing complicated structure in the interstellar calcium lines H and K have recently been published (*Astrophys. J.*, 97, 105; 1943). The spectra of fifty early-type stars have been studied with high dispersion (2·9 A./mm.) at the coudé focus of the 100-in. telescope at Mt. Wilson. More than 80 per cent of the stars show complex lines with up to five components. Various regions of the sky show different complexities of structure: towards Perseus and Scorpius single lines are frequent, with at most one satellite; whereas in the Orion, Sagittarius, Cygnus and Lacerta regions intricate structures are the rule. Stars close together in the sky exhibit lines of much the same structure. The evidence strongly suggests that interstellar calcium occurs to a great extent in discrete clouds, each with its own small peculiar motion but with little internal turbulence. Many of the spectrograms show also the additional narrow interstellar lines, atomic and molecular, discovered in recent years. Lines of Fe I seem to occur only in regions showing H and K strongly, whereas the diatomic molecules CN, CH and CH^+ may appear where calcium is not particularly abundant. The wave-length shifts given by these other lines show that they originate in one or other of the calcium clouds producing the H and K lines.

ANGLO-AMERICAN COLLABORATION IN THE CARIBBEAN REGION

THE report of the Anglo-American Caribbean Commission to the Governments of the United States and Great Britain for the years 1942–43, which has now been published*, leaves no room for doubt as to the successful start of this first attempt by Britain and the United States at joint control, and at the same time puts into a proper perspective that excessive concern regarding national sovereignty displayed in the statement issued in Washington with the joint communiqué announcing the creation of the Commission. The report itself is in three chapters, discussing in succession the organization of the Commission and the immediate and the long-term aspects of the Commission's programme, but is supported by the text of the joint communiqué of March 9, 1942, reports of the four meetings of the Commission of the Supply Officers' Conference, Jamaica, May 15–18, 1942, and of the Nutrition, Agriculture, Fisheries and Forestry Meeting in August 1943, which led to the creation of the Caribbean Research Council as an advisory body to the Commission. The objectives of this Council will be to survey needs, determine what research has been done, arrange for dissemination and exchange of the results of research, provide for conferences between research workers or extension workers, and make recommendations for further research and co-operation.

The organization thus far established consists of three interrelated units. First is the Commission itself, consisting of two sections of three members each, appointed by their respective Governments, and charged with the duty of helping the territories and colonies in the Caribbean in charting a system of co-operation which will reinforce their economy and society and give them added strength. The British section is closely affiliated with the Colonial Office in London, and with the Development and Welfare Organization in the West Indies. Second is the Caribbean Research Council, which provides the technical and scientific advice required to promote scientific, technical, social and economic advance, and is itself assisted by sectional committees, the first of which covers nutrition, agriculture, fisheries and forestry. The third unit of the organization is a regular system of West Indian Conferences, which is being inaugurated to provide for local consultation. This unit will be a standing body, meeting as and when required, with two delegates from each territory or group in the Caribbean area.

Following a series of meetings of the Commission and conferences in the West Indies, Washington and London, basic policies have been agreed upon in principle by an exchange of notes between the two Governments. The view is taken that the economic problems of the Caribbean should be regarded as regional rather than local. Generally speaking, a single-crop economy in the West Indies is undesirable. Mixed farming and animal husbandry should be encouraged everywhere, but a closed economic system should not be constituted. Inter-island trade should be encouraged throughout the entire Caribbean region. Advantage should be taken of fishing grounds in, and adjacent to, the Caribbean, and local fisheries with facilities for storage and distribution should be developed and organized. A greater vocational bias should be introduced into the educational system, and in addition to wide improvement of housing and sanitary conditions and an extensive school building programme, the inadequate transport to and within the Caribbean requires improvement. This will need co-ordination and planning on a broad scale. As an immediate and effective approach to the nutrition problem the Commission will investigate the provision of midday meals for children at school. The possibilities of industrial development, though limited, should not be overlooked.

On the immediate aspects of the Commission's programme, the report refers to the action taken to meet the food crisis which developed in the Caribbean in 1942. The Commission was responsible for establishing an organization for the bulk purchase of imported food necessities and assisted in developing a system of inter-island distribution. The measures taken led to a substantial increase in local food production and also to an alteration in the established eating habits of the peoples of the area. The fishery industries have received special attention, and the United States section of the Commission made a study of the sugar situation at the end of the summer of 1942 and formulated proposals which have been taken into account by the United States and the British Government in determining their policy with regard to the 1943 crop.

One outcome of the Conference of Supply Officers was the establishment of an Emergency Land Water Highway to provide a safe transport service from the mainland of the United States to Puerto Rico; in view of the improved situation with regard to submarine warfare, the service over the Hispaniole Highway and the maintenance of stockpiles were suspended in August 1943. The Conference also approved a recommendation that a single supply organization should be created for all the British Colonies, and the British Colonies Supply Mission has been established in Washington.

The long-range aspects of the Commission's programme demand long-term planning, and the basic problems are grouped roughly under the following headings: (1) conservation and utilization of natural resources; (2) development of systems of agriculture based upon improved efficiency; (3) development and maintenance of trade and communications among the Caribbean territories and colonies and with non-Caribbean areas; (4) provision of adequate housing and the improvement of public health; (5) full use of man-power in productive employment and the improvement of welfare among rural communities; and (6) broadening of education to include vocational instruction, the strengthening of public morale, and the promotion of 'self-help' and community co-operation.

The initial fishery survey is being followed up by a more detailed study in the south-eastern Caribbean, and commercial fishery research is being started. Special committees have already been formed under the Caribbean Research Council to report on land tenure and on the measures necessary to maintain diversified production. Arrangements have been made for the full collaboration of forestry services throughout the Caribbean with the United States Federal Forestry Research Institute in Puerto Rico, and the Research Council will assist in co-ordinating studies on forestry problems in the Caribbean and comparable areas. The Commission is giving attention to

* Report of the Anglo-American Caribbean Commission to the Governments of the United States and Great Britain for the Years 1942–1943. Pp. xi+94. (Washington: Anglo-American Caribbean Commission, 810 18th Street, North-West. London: Crown Agents for the Colonies, 1943.) 3*d*.

the removal of restraints to trade and travel between the British and the United States Virgin Islands. It has given full support to the work of the Federal Works Agency in Puerto Rico and the Virgin Islands, as well as to the programme of works projects drawn up by the Development and Welfare Organization for the British West Indies. At a conference in Washington in July 1943, it was decided that the Commission offered an effective medium for co-ordinating sanitation and health problems in the area, and a consultative committee was eventually formed for this purpose. Quarantine matters have received special attention, including the drafting of model quarantine legislation. This received detailed consideration at a Quarantine Conference in November 1943 under the auspices of the British West Indies Development and Welfare Organization in co-operation with the Commission. The primary objective of this Conference was to consider the adoption of uniform quarantine procedure throughout the British Caribbean Colonies in regard to maritime traffic, air navigation, and the adoption of model quarantine legislation.

Scientific workers will find particular interest in the detailed programme of research required on soil, water and forest conservation appended to the report on nutrition, agriculture, fisheries and agriculture which led to the formation of the Caribbean Research Council. In addition, the report itself includes detailed proposals for investigations on diet and health, food supply and nutrition, nutrition and public health, on animal husbandry, for which a long-range research programme is formulated, on fisheries, food processing, storage and marketing. Special stress is laid on research in animal husbandry, which has been wholly inadequate in the Caribbean; it is believed that no other investment would yield greater returns in terms of nutritional well-being than measures to increase the proportion of animal proteins in the diet, through improved and adapted animal husbandry and a stable and more efficient agriculture.

ROYAL COLLEGE OF SURGEONS

SCIENTIFIC REPORT

THE Scientific Report of the Royal College of Surgeons of England for the year 1942–43 gives the welcome news that no further specimens, Hunterian or College, were destroyed or suffered major damage during that year. The general condition of the specimens is satisfactory, but the task of looking after a large collection which is dispersed among various centres, some of which do not provide adequate or suitable accommodation, must be an arduous one, especially when so many of the staff are serving with the Forces. The need for better and more convenient accommodation for the specimens, with working room and technical facilities, is still urgent.

The report gives a list, covering six pages, of additions to the Museum, and an account of the research going on in the Bernhard Baron Research Laboratories under the direction of Prof. J. Beattie. During 1941–42 it was shown that plasma proteins can be removed rapidly from the blood-stream and can also enter the blood-stream very rapidly in considerable quantities. It was found that the rate of entry was so rapid that it could not be due to the synthesis of protein from amino-acids in the liver, and that plasma protein could be mobilized from tissues other than the liver. Since the end of 1942, the problem of increasing the rate of protein synthesis by the liver has been studied. Casein digests suitable for intravenous or subcutaneous administration are now being tried, with the object of increasing the rate of protein synthesis in the body. It is considered that such digests might be valuable for the treatment of burns, severe infections and fractures, in all of which conditions the loss of plasma proteins is considerable. The use of digests and pure amino-acids for the prevention of severe liver damage is also being studied.

In 1943 a study of toxic hepatitis was begun with the co-operation of the British and American Army authorities. It has been found possible to prevent the liver damage which occurs in syphilitic patients receiving arsenical treatment, and to reduce the period spent in hospital from 27 to 11 days and the convalescent period from three months to ten days.

Nerve injuries are being studied by a Leverhulme Research Scholar at Oxford and, at the suggestion of the Ministry of Health, a study was undertaken of raw materials which might take the place of absorbable catgut for sutures. A suitable raw material has been found, and this has passed laboratory and clinical trials. All the staff of the Buckston Browne Research Farm joined the Forces at the outbreak of the War, and the main laboratories there were taken over by the Emergency Public Health Service.

CLASSIFICATION OF ANTS

THE naming of the different species of ants and their classification into genera, tribes, subfamilies, etc., is but an artifice, a mere convenience, although an all-important one if we are to dispose of our knowledge of myrmecology to the best advantage. In fact, to-day, a knowledge of formicid nomenclature is essential to anyone wishing to make a reasonable acquaintance with myrmecology.

It is perhaps strange, then, that although some five thousand species of ants have been described and given names since the time of Linnæus, and these five thousand species distributed among approximately four hundred genera and four-score tribes belonging to eight sub-families, no myrmecologist has during the last thirty years published even a complete list of the ant genera, let alone any more comprehensive guide to formicid nomenclature. It is true that Emery in the "Genera Insectorum" (1910–25) covered the whole family, but although he provides the skeleton for the future taxonomic treatment of the group, it is sadly incomplete and in many cases out of date and inaccurate.

Emery lists only two hundred and sixty genera and fifty-three tribes, which he places in five subfamilies (*Dorylinæ* Leach, *Ponerinæ* Mayr, *Myrmicinæ* Lepeltier, *Dolichoderinæ* Forel and *Formicinæ* Forel) as against the modern eight; the three new subfamilies being the *Cerapachyinæ* Wheeler (previously a tribe *Cerapachii* Forel and later a section *Prodorylinæ* Emery of the *Ponerinæ* Mayr.), the *Leptanillinæ* (Emery) Wheeler, containing the solitary genus Leptanilla Emery earlier attributed to the *Dorylinæ* Leach, and the *Pseudomyrminæ* (Emery) Wheeler, previously considered as a tribe of the *Myrmicinæ* Lepeltier. Furthermore, the "Genera Insectorum" is scarce and difficult to obtain except at universities

and large institutions, where, of course, it may only be borrowed.

Wheeler's lists of the genera and their types (1911 and 1913) were therefore of great value, although incomplete and even more inaccurate than Emery's in the "Genera Insectorum".

The recent publication of Donisthorpe's "List of the Type species of the Genera and Subgenera of the Formicidae" (*Ann. and Mag. Nat. Hist.*, ii, **10**, 617, 649, 721; 1943) is therefore an event of considerable importance. For the first time there is an authoritative, complete (so far as is known) and easily obtainable list of the genera and subgenera of ants. Furthermore the tribe, subfamily and also, where it occurs, synonomy of each of the genera listed are given. The type species are listed in each case, together with the type locality.

It is difficult to review such a list without entering into detail which would be out of place here, but which I hope to discuss elsewhere. A few points may, however, be mentioned. The use of the generic name Lasius Fabr., a synonym for Acanthomyops Mayr (five species of which are found in Great Britain), perpetuated by Wheeler and Emery, should now cease for good and all. Fabricius's name sinks on account of Jurine's earlier one. Ruzsby's subgenus Lasius (s.g. of Lasius Fabr. Acanthomyops Mayr.) also sinks to Morrice and Durrant's Donisthorpea. It is nice to see Crematogaster Lund for once spelt correctly and not as in Wheeler's "Ants" (1910) and Forel's "Social World of the Ants" (London, 1927) with an 's', namely, Cremastogaster, which is meaningless. Emery's mis-spelling of Chtonolasius Ruzsby (copied by Donisthorpe in his "British Ants", 1927) has also been corrected.

The function of nomenclature is to aid and simplify the work of the zoologist, not to confuse him and make his task more complex. It is a mechanism for handling the data appertaining to, and not a fundamental part of, biology, and as such the taxonomy of a group should be well-ordered, comprehensible and easily accessible. Donisthorpe is therefore to be congratulated on this attempt to produce order out of chaos and to make accessible that which has been beyond the reach of all but the experienced myrmecologist—in fact, Donisthorpe himself and less than half a dozen others in the world.

B. D. WRAGGE MORLEY.

PELAGIC FORAMINIFERA

WE owe much of our recent knowledge of the biology of the Foraminifera to Dr. E. H. Myers. His new publication* is a peculiarly beautiful example of his work, embracing the complete life-cycle of Tretomphalus and its activities observed both in Nature and in cultures. The life-cycle includes an orderly succession of sexual and asexual generations in which two distinct types of individuals and three types of tests are involved. Typically benthonic microspheric (asexual) and megaspheric (sexual) individuals are produced, the latter becoming pelagic prior to the discharge of the gametes. The test of the pelagic phase has a globular terminal chamber, perforated by large pores, and contains a gas-filled float, the gametes passing out of the pores. The zygotes are formed by the fusion of gametes from different parents, the latter approaching one another and their amœboid pseudopodia anastomosing—an unusual occurrence in the Foraminifera. This association ensures the fertilization of a maximum number of gametes, which settle on the bottom and produce microspheric tests. So the life-cycle proceeds.

Tretomphalus is shown to be significant only as a convenient category in which to place the pelagic stage of species which are now included in either the genus Discorbis, family Rotaliidæ, or the genus Cymbaloporetta, family Cymbaloporidæ. Much confusion in nomenclature has been caused by the polymorphic nature of these tests, and this work should contribute largely to a more natural classification.

Observations on feeding show that swiftly moving organisms, such as nauplii, ciliates and veligers, are not captured, although these can be utilized as food when crushed and placed in the vicinity of the test. On the other hand, grazing on diatoms and other unicellular algæ on the walls of the dish is usual, and inclusions of these can be seen in sections. Similar sections of material from the sea show that the natural food is the microflora both from the water or on the substratum fixed on the surface where the animals live.

Interesting accounts are given of the formation and growth of the tests. Under optimum conditions in cultures maintained at 20° C., about forty-two days are required for an asexually produced individual to form a test consisting of 13–17 chambers.

The illustrations which accompany this paper, both photographs and drawings, are of great beauty and clarity, and special mention should be made of the photograph of dispersal of the juveniles and the disintegration of the empty test of the microspheric individual which produced them: also the figure of the life-cycle of *Tretomphalus bulloides*.

* Biology, Ecology and Morphogenesis of a Pelagic Foraminifer. By Earl H. Myers. Stanford University Publications. University Series. Volume IX. Number 1. Biological Sciences. Stanford University Press. 1943.

RECENT AMERICAN ARCHÆOLOGY

EUROPEAN archæologists are too often apt to forget that the prehistoric period continued in many parts of the world, America included, until about the day before yesterday. Moreover, just because the later time limit of the study is so recent, much more evidence can frequently be collected than in the case of the very remote cultures, and thus a picture in greater detail constructed. The fact, then, that Waldo R. Wedel's recent archæological investigations in Platte and Clay counties, Missouri (United States National Museum, Bull. 183), deal with finds which in western Europe would be classed as post-medieval in date, does not make them any less interesting or less important. The interest and importance of the ruins at Zimbabwe in Southern Rhodesia were not lessened when it was shown that their date was anything but prehistoric in our sense of the word.

Mr. Wedel is concerned with village sites and two kinds of burial mound. He suggests the presence in the area of two different cultures. One (the Renner village site is the type site) shows definite relationships with certain "Northern Elemental Hopewellian Manifestations" such as those found in the Illinois valley and south-western Wisconsin, the other (the Steed-Kisker site is the type station) recalls the Nebraska culture, characteristic of the Missouri River bluffs in eastern Nebraska and south-

western Iowa, being a local variant of the late Middle Mississippi culture. The stone-chambered burial mounds containing dolicocephalic remains are classed with the first-named culture, the earth mounds with the latter. Actually, at Steed-Kisker itself the dead were buried in graves and large earth mounds are absent. When contrasting the material culture from the two classes of sites, no very startling difference is observable, but there are distinctions noticeable in the pottery types, as well as in other classes of finds. An appendix on the types of human skeleton collected is written by T. Dale Stewart.

Once again we are dealing with local investigations on the more recent archæology of America. So much material having survived for this period in the New World, it is not yet time for a major work of synthesis, but volumes such as the one under review will be the source of information for future compilers of the history of the United States during the centuries immediately preceding the arrival of the Europeans.

M. C. BURKITT.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, March 13

SOCIETY OF CHEMICAL INDUSTRY (YORKSHIRE SECTION) (in the Chemistry Lecture Theatre of the University, Woodhouse Lane, Leeds), at 7 p.m.—Dr. T. H. Blakeley: "Graphical Methods of Treating Technical Problems".

ASSOCIATION OF AUSTRIAN ENGINEERS, CHEMISTS AND SCIENTIFIC WORKERS IN GREAT BRITAIN (at the Austrian Centre Swiss Cottage, 69 Eton Avenue, Hampstead, London, N.W.3), at 7.15 p.m.—Dr. K. Weissenberg: "Chemical Constitution and Physical Properties of Materials".

Tuesday, March 14

CHADWICK PUBLIC LECTURE (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 2.30 p.m.—Dr. S. A. Henry: "Medical Supervision in Industry in Peace and War".*

INSTITUTION OF CHEMICAL ENGINEERS (joint meeting with the CHEMICAL ENGINEERING GROUP) (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. W. K. B. Marshall: "The Welded Joint in Non-Ferrous Chemical Plant".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE (in Committee Room 14, House of Commons, London, S.W.1), at 3 p.m.—Discussion on "A Scientific Policy for British Agriculture, particularly in relation to Nutrition" (Speakers: Prof. F. L. Engledow, Prof. Miller and others).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. A. R. Todd, F.R.S.: "The Mode of Action of some Vitamins", 2.*

INSTITUTION OF CIVIL ENGINEERS (joint meeting with the INSTITUTION OF MECHANICAL ENGINEERS) (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Symposium on "Contractors' Plant".

Wednesday, March 15

INSTITUTE OF METALS (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 11 a.m.—Thirty-sixth Annual General Meeting; at 2.30 p.m.—Dr. W. Hume-Rothery, F.R.S.: "Modern Views on Alloys and their Possible Application".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. J. N. Dean: "Gutta Percha and Balata, with Particular Reference to their Use in Submarine Cable Manufacture".

SOCIETY OF CHEMICAL INDUSTRY (PLASTICS GROUP) (joint meeting with the PHYSICAL SOCIETY) (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 2.30 p.m.—Dr. W. T. Astbury, F.R.S.: "The X-Ray Examination of Plastics".

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Annual General Meeting. Prof. W. G. Fearnsides, F.R.S.: "The Practice of Geology" (Anniversary Address).

ROYAL INSTITUTE OF CHEMISTRY (at 30 Russell Square, London, W.C.1), at 3 p.m.—Annual General Meeting. Mr. P. A. Houseman: "Licorice—Putting a Weed to Work" (Streatfeild Memorial Lecture).

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, South Kensington, S.W.7), at 4.30 p.m.—Major H. C. Gunton: "Report on the Phenological Observations in the British Isles from December 1942 to November 1943".

INSTITUTION OF ELECTRICAL ENGINEERS (LONDON STUDENTS' SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 7 p.m.—Mr. H. W. H. Warren: "Electrical Engineering Research" (Student's Lecture).

Thursday, March 16

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Sir John Russell, F.R.S.: "Europe's Changing Peasantry".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. C. R. Harington, F.R.S.: "Newer Knowledge of the Biochemistry of the Thyroid Gland" (Ninth Pedler Lecture).

SOCIETY OF CHEMICAL INDUSTRY (AGRICULTURE GROUP) (joint meeting with the BIRMINGHAM SECTION) (at the Chamber of Commerce, New Street, Birmingham), at 2.30 p.m.—Mr. P. Parrish: "Our Fertilizer Industry; with Special Reference to Modern Methods of Manufacture of Calcium Superphosphates, Ammonium Sulphate and N.P.A. Granular Fertilizers".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 3 p.m.—Prof. H. W. Turnbull, F.R.S.: "Recent Advances in the Theory of Forms".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. P. Schiller: "An Analysis of the Load on a Modern Electricity Supply System".

Friday, March 17

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Mr. Howard Marryat: "Evolution of the Pocket Watch".*

INSTITUTION OF ELECTRICAL ENGINEERS (MEASUREMENTS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. R. Dell: "Developments of Railway Signalling on London Transport".

INSTITUTION OF MECHANICAL ENGINEERS (in conjunction with the APPLIED MECHANICS GROUP) (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Symposium on "Some Modern Aids in the Investigation of the Behaviour of Materials, Mechanisms and Structures".

BRITISH ASSOCIATION OF CHEMISTS (NORTH-EAST SECTION) (in the Chemistry Lecture Theatre, King's College, Newcastle-upon-Tyne), at 6 p.m.—Dr. F. G. Mann: "Some Aspects of the Organic Chemistry of Phosphorus and Arsenic" (Tilden Lecture of the Chemical Society).

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (in the Lecture Theatre of the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—The late Dr. W. H. Hatfield, F.R.S., Mr. L. Rotherham and Miss E. M. A. Harvey: "Further Experiments on the Damping Capacity of Metals".

Saturday, March 18

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 2.30 p.m.—Mr. W. J. Meredith and Dr. G. J. Neary: "The Production of Isodose Curves and the Calculation of Energy Absorption from Standard Depth Dose Data"; Mr. P. H. Flanders: "A Demonstration of an Optical Contour Finder".

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 2.30 p.m.—Dr. H. M. Finniston and Mr. T. D. Fearnehough: "The Physical and Mechanical Properties of Segregates".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ELECTRICAL ENGINEER (location, Middle East)—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.767A) (March 15).

CHEMICAL ENGINEER, to assist in the design and testing of plant for the manufacture of various chemicals, mainly organic—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2040.XA) (March 15).

TEACHER to teach mainly MECHANICAL DRAWING in the Junior Technical School, with some MATHEMATICS and/or WORKSHOP PRACTICE (wood or metal)—The Principal, County Technical College, Gainsborough, Lincs. (March 17).

ASSISTANT TO THE ADVISORY CHEMIST—The Chief Advisory Officer, Agricultural Advisory Department, The University, Manchester (March 18).

GRADUATE MISTRESS (MATHEMATICS) for Barrett Street Technical School, Oxford Street, London, W.1, and Maidenhead—The Education Officer, T.1, County Hall, Westminster Bridge, London, S.E.1 (March 18).

HEADMASTER OF THE PRE-APPRENTICESHIP COURSES FOR THE BUILDING TRADES recently established in Aberdeen—The Director of Education, Education Offices, Castle Street, Aberdeen (endorsed 'Pre-Apprenticeship School') (March 18).

PRINCIPAL—The Clerk to the Governors, Harper Adams Agricultural College, Newport, Shropshire (March 18).

PROFESSOR OF MECHANICAL ENGINEERING in the Benares Hindu University Engineering College—The Secretary, Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1 (March 18).

COMMISSIONS IN H.M. FORCES (a limited number) will be granted to candidates who are University-trained Biologists, preferably men with some experience of malaria or entomology—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. ONF.2057A) (March 18).

UNIVERSITY CHAIR OF ANATOMY tenable at St. Mary's Hospital Medical School—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (March 20).

TUTORS (2, men, preferably unmarried) at the Makerere College, Kampala, Uganda; Post 1, GEOGRAPHER to teach in New Arts Course, should be specially qualified on the Humanistic (i.e., Social and Economic) side of the subject; Post 2, CHEMIST qualified to teach both Organic and Inorganic and with a special interest in Biochemistry—The Secretary (IPR/CA), Board of Education, Belgrave Square, London, S.W.1, or The Secretary, Scottish Education Department (Branch Office), 29 St. Andrew Square, Edinburgh 2 (March 21).

CIVIL ENGINEERS by a firm of Contractors in the Near East—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. EA.803.XA) (March 22).

MUSEUM ASSISTANT (man or woman) IN THE DEPARTMENT OF ZOOLOGY—The Secretary, Bedford College for Women, Springfield, Sidgwick Avenue, Cambridge (March 22).

DEPUTY BOROUGH ELECTRICAL ENGINEER—The Borough Electrical Engineer, Electricity Works, Warrington (endorsed 'Application for Deputy Borough Electrical Engineer') (March 24).

TEACHER (man or woman) at the Cannock Chase Mining College, mainly for the daytime teaching of Science—The Director (H), County Education Offices, Stafford (March 25).

READERSHIP IN MINERALOGY—The Registrar, University Registry, Oxford (April 8).

WAYNFLETE PROFESSORSHIP OF METAPHYSICAL PHILOSOPHY—The Registrar, University Registry, Oxford (April 13).

PROFESSORSHIP OF ENGINEERING SCIENCE—The Registrar, University Registry, Oxford (April 30).

CHAIR OF PHILOSOPHY at the University of the Witwatersrand, Johannesburg—Dr. William Cullen, 4 Broad Street Place, London, E.C.2 (May 1).

DIRECTOR OF THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

CHAIR OF NATURAL PHILOSOPHY, United College, St. Andrews—The Secretary, The University, St. Andrews (June 15).

LECTURER IN MECHANICAL ENGINEERING at the Norwich City College and Art School—The Director of Education, City Hall, Norwich.

GRADUATE ASSISTANT to teach chiefly PHYSICS and MATHEMATICS in the Thomas Richards Technical Institute, Tredegar—The Director of Education, Higher Education Department, County Hall, Newport, Mon.

MATHEMATICS MISTRESSES (2) at the Jerusalem Girls' College, and a MATHEMATICS MISTRESS at the English High School, Haifa—The Secretary, Jerusalem and the East Mission, 8 St. Thomas Street, Winchester.

SENIOR LECTURER IN THE PHYSIOLOGY DEPARTMENT—The Secretary, University of Edinburgh, Summerhall, Edinburgh 9.

WOMAN GRADUATE to take charge of analysis of original material on food purchases and consumption and its presentation in statistical tables—Appointments Department, Ministry of Labour and National Service, Sardinia Street, London, W.C.2 (Quoting Reference No Q.M.33).

SEX TEACHING IN SCHOOLS

ONE result of war-time conditions has been the focusing of attention on the problems of sex guidance. This is not essentially a war-time question, and it should be viewed in perspective as part of the normal education of normal people in normal times, but the unsettled social conditions of recent years have brought the matter into prominence.

Among those who have been giving it attention are the rank-and-file teachers of Great Britain, who have expressed their willingness to play their part. This ferment has worked its way up to the top, and is beginning to produce results in the governing bodies of the various teachers' professional organizations. At their January meetings the Associations both of Assistant Masters and of Assistant Mistresses passed resolutions pledging their support, and now the National Union of Teachers has issued an important statement*.

The advance represented by this statement may be gauged by the fact that whereas in 1933 it was the considered opinion of the Executive of the National Union of Teachers "That the giving of class sex instruction is undesirable and against the best interests of the children in the schools", it is now concluded that "The position in relation to sex instruction has been considerably modified. Given the right conditions the information of the 'facts of life' can be taught in schools."

While recognizing that both teachers and parents have in the past tended to evade their responsibilities in this connexion, the pamphlet correctly reasons that "In the absence of a proper method of instruction, however, there is the real danger, too often experienced, that scraps of information or misinformation are liable to be whispered in a lewd or vulgar manner from one to another among pupils in a school"; and that "It would appear, therefore, that danger may lie less in the dissemination of knowledge than in its perversion and vulgar distortion."

Proceeding to a consideration of the content of sex education, the statement quotes with apparent approval an interesting paragraph from the *Health Education Journal*: "Sex education is more than the mere imparting of knowledge. Factual information is indispensable, but it is also necessary to interpret for the pupils the relationship between the facts of human physiology and the conventions of human society. Moreover, even an understanding of the origin and value of certain conventions will not ensure the living of a fine sex life. The children must be inspired with a feeling of the excellence of sex and of its immense potentialities. As in the pioneer days of widespread elementary education there was the slogan of the 'three R's', so sex education might well be characterised as the 'three I's'—sex information, sex interpretation and sex inspiration".

After pointing out that the nature study which is included in most school curricula provides a firm foundation for further instruction, the pamphlet then

* Sex Teaching in Schools. Statement by the Executive of the National Union of Teachers. Obtainable from the N.U.T., Hamilton House, Mabledon Place, London, W.C.1.

discusses the question of the extent to which school biology courses should deal with our own species. In this connexion it quotes the recent contention of Mr. Cyril Bibby (education officer of the Central Council for Health Education) that *Homo sapiens*, instead of being obscurely tucked in at the end of a course in which Amoeba, Hydra and Rana hold the places of honour, will be introduced in the first year of the post-primary school. Information about the biology of reproduction in plants and lower animals is an excellent adjunct to information about sex in humans, but is no substitute for it. It must be remembered that in many children there is an actual resistance against knowledge, due to fears and guilt-feelings, and if we leave a gap in our description they will fill it with the most fantastic imaginings. Children are interested in the functioning of their own bodies, and in a series of lessons on human physiology, sex and reproduction may be introduced in their proper place without undue emphasis. It is a sound principle that "reproduction should be regarded as a normal function of organisms, and no attempt should be made to isolate it or single it out for special attention".

The next problem is that of deciding who should be responsible for imparting the necessary information. It is recognized that parents should play an important part, but sight is not lost of the fact that "many parents do not give it and that many have neither the knowledge adequate for the purpose nor the skill to impart what knowledge they have". In these circumstances, the statement goes on to ask, "Should doctors or nurses be asked to visit the schools for this purpose ?" and gives a clearly negative reply. Many weighty arguments are marshalled against this proposal, all leading to the conclusion that "if this direct teaching is given, the teacher is the one on whom the duty is likely to devolve". It is very important that this point be borne in mind, for there are many who, while agreeing that sex education is desirable, tacitly assume that medical men should be responsible for it. By far the majority of medical men are not trained educationists, and there is also a real danger in bringing in a doctor, who still to the lay mind is associated chiefly with disease, to talk on something which is natural and healthy.

But the teachers themselves will need much preparation; and it is with pleasure that one reads recommendations 6, 7 and 14 of the pamphlet. These are of sufficient importance to warrant full quotation :

"6. Steps should be taken to ensure a greater supply of teachers fully qualified to teach biology and to afford facilities and provide adequate equipment for biological teaching to be given."

"7. Greater attention to the human aspect of biology should be given during teachers' training courses."

"14. Those teachers who wish to engage in the teaching of this subject should be afforded facilities for attendance at lectures or refresher courses to prepare themselves as fully as possible for the task."

Teachers will be faced with the decision whether to give instruction to individuals, to small groups, or to ordinary classes. The advantages and disadvantages of each type of approach are discussed, and although the pamphlet avoids any clear-cut decision, the weight of the argument appears to be in favour of dealing with sex in full class—even, it would appear, where the classes happen to be mixed.

Emphasis is quite rightly laid upon the importance of co-operation between teachers and parents; but it is doubtful if the Executive of the National Union of Teachers has quite caught up with the times when it states that "it is at the present stage of public opinion imperative" to "obtain the consent of the parent before it [that is, sex instruction] is given, and to make the position quite clear to all parents that if they do not wish for their children to receive the instruction they are fully entitled to say so, and the teacher will arrange accordingly". The fact is, that many schools do not ask prior consent, and that very rarely is there any complaint. Parents generally are overwhelmingly grateful to schools for dealing with this matter. Nevertheless, in some areas it may be wise to obtain consent.

It is perhaps pertinent to inquire whether the Executive has given sufficient weight to the arguments against granting this right of withdrawal. In the first place, the very act of asking consent can scarcely fail to imply that there is something a little doubtful about this instruction, something which makes it necessary to isolate it from the rest of the child's education—despite the emphasis to the contrary elsewhere in the pamphlet. The matter is considered in a recent article* from which we may quote: "Thirdly, a fine crop of problems arise if any replies to the question are in the negative.

(*a*) What do you do with the child who is not to attend the course ?

(*b*) What does the rest of the class think about this withdrawal ? Are all your careful plans to be frustrated as this subject is shown to be a queer, secret thing after all ?

(*c*) The child who is to be isolated will get the information from the other members of her class, second-hand, probably somewhat distorted and certainly in the wrong setting; her feelings of guilt will be intensified; her relationship with her parents will be marred.

(*d*) Further, the prohibition suggests that the psychological atmosphere in which the child lives is already difficult: if this is so, then the school seems to be her only hope. Where the parents say they wish to tell the child themselves, they seem to have left things rather late. Beginnings must be made in the home in early childhood; left until adolescence is reached, a barrier has been set up between parent and child that may be insurmountable: again, the school seems to be the child's best chance."

On the whole, however, the statement by the National Union of Teachers represents a marked step in the right direction, and, coming as it does from one of the most powerful professional organizations in the country, should bear very fine fruit.

Frontiers in Cytochemistry

The Physical and Chemical Organization of the Cytoplasm. Edited by Prof. Normand L. Hoerr. (Biological Symposia, Vol. 10.) Pp. vii+334. (Lancaster, Pa.: The Jaques Cattell Press, 1943.) 3.50 dollars.

THE well-known jibe that the specialist is one who knows more and more about less and less may be taken in its complimentary sense by workers in many branches of science. Those who are endeavouring to determine the biochemical nature and enzymic composition of the microscopic and submicroscopic components of living cells belong to this category, and now they are at least beginning to show signs of penetrating some of the mysteries which beset the isolation and identification of anything so small and so sensitive as the protoplasmic particles and granules.

Ten years ago, Dr. R. R. Bensley retired from active occupation of the chair of anatomy in the University of Chicago. During the preceding forty years he had contributed largely to the study of cytological problems, to glandular secretion, and to advances in histological technique. Among his distinguished pupils was E. V. Cowdry; and his successor is N. L. Hoerr. On his retirement from academic duties, Dr. Bensley began work on cytoplasmic components, which Dr. Hoerr considers to be perhaps the most significant contribution of a long and very active career. He celebrated his seventy-fifth birthday last year, and in honour of this event a symposium was held at Chicago in November. The theme was the chemical and physical organization of the cytoplasm, the contributors were all active and distinguished investigators in this field, and the present volume is the record of the papers given, which incidentally have been brought fully up to date and constitute a most useful and comprehensive collection, especially valuable in a field such as this where publications are liable to be scattered over very many journals.

Dr. Bensley's guiding principle has been the separation of separable things before proceeding to their analysis. In 1934 he succeeded in separating granules considered to be mitochondria in a state of purity from liver cells, a feat in which Warburg in 1912 had been partially successful and which enabled Warburg to state that these particles contributed to the oxygen uptake of saline extracts of liver. Later, A. Claude, and independently A. Lazarow in Bensley's laboratory, discovered and isolated yet smaller, submicroscopic particles contained in liver and other cells. All these workers make excellent contributions to the book; but their accounts would be much clearer to follow if they could agree to a common system of nomenclature. Thus the "mitochondria" of Bensley and his colleagues are the "secretion granules" of Claude, while the latter's "small particles" or "microsomes" are called "submicroscopic lipoprotein particles" by the Chicago school. Lazarow states that these smaller bodies are red; but Claude, who has got them from other sources besides liver, finds that they are light to dark amber in colour. They are about 50–300 mμ in diameter, whereas the larger granules are 0·5–1 μ. Although, as Claude has shown, both contain ribosenucleoprotein and phospholipins, there are quantitative differences in their composition. The larger granules ("mitochondria") disintegrate rapidly in distilled water, yielding submicroscopic particles closely resembling the "small particles" already mentioned. Possibly the latter are concerned in the formation of the larger granules, which contain, however, much less lipin. Both contain inositol to the extent of 2 per cent of the lipin content. The zymogen granules isolated by Claude from the pancreas closely resemble in composition and in their properties the larger granules described above.

So far, organic structures which exhibit the property of self-duplication seem to contain nucleic acid, as, for example, the viruses of plants, Shope papilloma virus, and, it is claimed, Rous chicken sarcoma agent and probably the mouse-milk cancer factor (Kahler *et al.*, *J. Nat. Cancer Inst.*, 4, 37; Aug. 1943). This prompts Claude to suggest that perhaps these particles isolated from cytoplasm, particularly the submicroscopic ones, may be endowed with this property also, and may participate actively in cell division.

These cytoplasmic components have, according to recent studies, distinct metabolic activities of their own. Hotchkiss and Hogeboom have shown that *d*-aminoacid oxidase activity is localized in the "secretory granules" but absent from the "small particles" of guinea pig and rat liver. Barron, who contributes a valuable 40-page synopsis of present knowledge of biological oxidation mechanisms, finds in experiments with Lazarow that partially separated mitochondria (secretion granules of Claude) oxidize succinic and glutamic acids, the latter more vigorously, but the nuclear concentrate is notable for its high succinoxidase activity, while the alcohol oxidase diffuses into the aqueous phase during centrifugation. Dounce has found that liver nuclei contain cytochrome oxidase, esterase, phosphatase, arginase, and lactic dehydrogenase, and more recently Lan (*J. biol. Chem.*, 151, 171; Nov. 1943) has added *d*-aminoacid oxidase and uricase to the list. Bartlett has shown that, while the tomato seed contains carboxylase, its coenzyme appears only on germination, and it is evident that if the type of technique now being developed could be applied to locating the origin of coenzymes and enzymes within the living cell, it would immediately acquire enormous potentialities.

K. G. Stern has an interesting chapter on various "macromolecular particles" which he has separated and analysed. Like much of the work described in this book, this is naturally an application of modern developments in high-speed centrifugation and other technical advances. The British reader is a little dazzled by the resources of this kind at the disposal of his American colleagues, so that it is something of a relief to find that Mirsky and Pollister, at the Rockefeller Institute, have a chapter in which they do quite a lot with a saline extract of tissue and "a glass rod with a crook at the base". With these homely accessories they seem to have separated nuclear nucleoprotein in a high degree of purity. Contrary to Stedman and Stedman (NATURE, Sept. 4, 1943), they believe that "threads of chromatin (chromosomes ?) assay practically 100 per cent nucleoprotein; that the nucleoprotein is, in fact, the substance of the chromosomes".

There is so much in this book that one can only catalogue other contributors here. These include N. L. Hoerr (isolation methods), H. W. Beams (ultracentrifugal studies), R. Chambers (intracellular 'Ringer' solution), E. V. Cowdry (cytology of carcinogenesis), I. Gersh and D. Bodian (histochemical changes in motoneurons), O. H. Lowry (cytoplasmic electrolytes), F. O. Schmitt, C. E. Hall and M. A.

Jakus (electron microscope studies on fibrils), and G. H. Scott (mineral distribution and localization in the cytoplasm). This excellently produced book contains a valuable collection of current individual adventures into the domain of the cell interior.

F. DICKENS.

REGIONAL EDUCATION

The Book of Buchan

(Jubilee Volume.) A conjoint Publication in five Sections on the North-East in Ancient, Medieval and Modern Times, by sixteen Contributors and eight Chapters by the Editor. Edited and arranged by Dr. J. F. Tocher. Pp. xii+330+44 plates. (Aberdeen: Dr. J. F. Tocher, 41½ Union Street, 1943.) 21*s*.

EDUCATION begins at home and, by stages which become more formal and circumscribed with each advance, proceeds to the primary and to the secondary schools, and for a fortunate few leads to the university. But outside the formal education, and for many more potent than it in building character and creating loyalties, almost as powerful as the home, is the influence of the geographical region in which impressionable years are spent. The Scottish clans were regional units, and it is this fealty to place which has been guided to the service of a wider patriotism in the territorial regiments, and which, so long as recruitment was more or less confined to the regiment's area and dilution by 'foreigners' was avoided, ensured for each regiment its own distinctive and cherished *esprit de corps*.

Although in the press of the ordinary school's curriculum the regional interest as a basis for the development of a wider instruction has scarcely found a place, it has nevertheless played a notable part in that education which begins when school-days end. It is represented in parish histories, such as Sir John Sinclair's "Statistical Account of Scotland" (1791) and its successor of the following century, "The New Statistical Account", in county histories, such as the ambitious "Victoria History" of English counties, and in innumerable local histories, of varied merit. The aim in every case is similar, to put on record regional developments and achievements and so, in deepening knowledge, to confirm and strengthen pride of place; and if this is to be done effectively the history must cover many aspects, and in such a manner as to appeal to the interest of the plain man.

In 1910 the Buchan Club issued such a history, "The Book of Buchan", to celebrate its majority. It was a local history fit to arouse the enthusiasm of the people of north-eastern Scotland. Now a second "Book of Buchan" commemorates the jubilee of the Club. Like its predecessor, it is edited by Dr. J. F. Tocher, who has skilfully contrived into a consecutive series the work of many contributors, using his own editorial articles as the constructional cement. Twenty-six articles elaborate or supplement the subjects of the earlier book, dealing in groups with the natural history, prehistory, literary, medical and martial celebrities, selected miscellanies of history and events.

The majority of the contributions are what they were intended to be, primarily of local interest, though the development of any region has its own significance to its neighbours and to the nation of which it forms a part. Of wider interest may be mentioned Prof. Gordon Childe's resetting of the prehistoric archæology of the district in the light of modern knowledge, the editor's records of the plague which, in 1647, caused professors and undergraduates of King's and Marischal Colleges to migrate respectively to Fraserburgh and Peterhead, Dr. Milne's account of the rise and decline of the whale-fishery of Peterhead, founded upon the publications of the late Dr. R. W. Gray, and Prof. R. A. Fisher's suggestion that with the gradual impoverishment in human quality of local areas, the character and destiny of each locality will come to depend less upon the regional spirit, and more upon the evolution of the nation as a whole.

The "Book of Buchan" is an excellent example of what may be done to consolidate a local heritage, in a region still markedly individual and distinctive.

JAMES RITCHIE.

PLANT TISSUE CULTURE

A Handbook of Plant Tissue Culture

By Dr. Philip R. White. Pp. xiv+277. (Lancaster, Pa.: The Jaques Cattell Press, 1943.) 3.75 dollars.

IT is rare, even in these days of specialized studies, that circumstances permit an investigator to present a 'first book' on pioneer work in any subject. This opportunity has come to Dr. White, and he has taken full advantage in the presentation of an admirable book. In the past, text-books of tissue culture have given the quite erroneous impression that only animal biologists have any interest in the subject or could derive anything of value from its study. Dr. White presents the case of the plant biologist, based on 457 references, with commendable force. He compresses into this relatively small volume the 'high spots' of plant tissue culture up to the present, in which he has himself played an outstanding part, and points out wide fields of interest for future research.

The most valuable part of the book, from a strictly utilitarian point of view, is undoubtedly the chapters dealing with matters of technique. Here we have, for the first and possibly last time, as befits a pioneering work, a most detailed description of the facilities necessary for starting and maintaining cultures, of the nutrient solutions needed, which Dr. White has himself set up as the accepted standard, and of a host of those small details of technique so vitally important and so often overlooked. Emphasis is rightly laid on scrupulous cleanliness, and here, as in the rest of the book, the fruits of years of experience are packed in a remarkably small space. For this section of the book alone, it is to be recommended to those who anticipate using this new tool, as a clear and stimulating exposition. Dr. White proves himself, however, more than a mere guide—he is also philosopher and friend—and the opening chapters in particular, dealing with the philosophical and historical approaches to the subject, are well conceived as placing this new technique in its true perspective against the general background of plant biology.

The last two short chapters are devoted to problems which have been attacked successfully by tissue culture methods; mineral nutrition and a study of nutrients generally both as regards their necessity for the maintenance of growth and as regards the quantitative reaction of tissues to specific doses of specific nutrients; water secretion in excised roots, giving a new stimulus particularly to the meaning and importance of 'root pressure'; tropisms in roots; growth of individual cells; and the effect of viruses

and other pathogens on the host tissue. Studies are described in the realm of morphogenesis, and this isolation of tissues from the morphogenetic influences of neighbouring tissues will undoubtedly form the soundest approach to questions of the effects of growth substances, chemical gradients, and so on.

It cannot be doubted that the isolation and successful growth of tissues is of great promise in many fields of plant science, or that the study has now reached the stage at which rapid advances are to be expected. It seems, in fact, probable that only the difficulties, real and imagined, of the culture of plant tissues has prevented the use of this method in many problems which can scarcely be solved by any other means. This book does much to remove these difficulties by emphasizing the precautions to be taken and the pitfalls to avoid, and its service to science in this way alone can scarcely be estimated at this time.

The book is to be heartily recommended to all plant biologists interested in new developments as a volume which can be read with pleasure as well as profit. It is illustrated by numerous photographs of excellent quality (including portraits of the principal workers in the field of tissue culture), and the presentation is of high standard. R. D. Preston.

ASPECTS OF REHABILITATION

Rehabilitation of the War Injured

A Symposium. Edited by Dr. William Brown Doherty and Dr. Dagobert D. Runes. Pp. 684. (New York: Philosophical Library, Inc., 1943.) 10 dollars.

During the past few years, the word 'rehabilitation' has come into common usage, but there does not appear to be a clear definition of its exact significance. This doubt is evidently shared by the contributors to this symposium, and we are presented, therefore, with articles based on almost every shade of its meaning. This variation in interpretation carries us from excellent chapters on the creation and maintenance of physical and mental fitness in those who have suffered from extensive war injuries, down to much less excellent sections upon highly specialized surgery.

There may be justification for considering that surgical repair is necessarily part of rehabilitation; it may, indeed, be all that is necessary. On the other hand, rehabilitation may more urgently follow conditions which do not require preliminary operation. That great part of the book, therefore, which deals with the technique of reconstructive and plastic surgery would seem to refer chiefly to those patients in whom no serious after-treatment is of importance. Parts of this section fulfil no particular purpose. They are couched in vague terms and end by being neither a technical description which might be of surgical value, nor yet sufficiently free from detail to make them valuable for anyone whose interest is not primarily surgical. Worse still, the contributors of some of these chapters have not considered it desirable to keep within the elastic limits of such a title as the editors have chosen, and have diverged to describe the treatment of defects which have no relation to war or its sequelæ. It may be that the writers themselves are not to blame for this, as it appears from the extensive list of acknowledgments that a great deal of the material has been collected from already published sources. This may also account for the very marked lack of clarity in the illustrations.

It should not be supposed, however, that this adverse criticism is applicable to the whole symposium. Many of the sections are concerned with specialized after-treatment which is rendered necessary by reason of some particular injury—the loss of sight, of hearing, or of a limb. Others deal fully with the specialized aspects of such treatment, and naturally enough the amount of stress laid on any particular method is in direct relation to the enthusiasm of its exponent.

The multiplicity and diversity of the views expressed are but an index of the magnitude of the problem, and one cannot help feeling that even if this volume does not answer the questions it raises, it should do much to stimulate coherent thought upon a subject which is, at the moment, only vaguely appreciated. In other words, when rehabilitation ceases to be a political catchphrase and is returned to the specialists who practise its component sections, we may well look forward to a great improvement in both the degree and duration of disability from which an injured man may suffer.

If this book is intended for the general public, it will, in the reviewer's opinion, leave them interested but somewhat confused. If, on the other hand, it is directed towards the medical profession, it should go far towards convincing them that the solution of the problem lies almost entirely in the integration of their various efforts into one harmonious whole.

SYMPOSIUM ON CANCER

Selected Papers from the Royal Cancer Hospital (Free) and the Chester Beatty Research Institute

Published by order of the Governors of the Royal Cancer Hospital (Free), London. Vol. 2. Pp. viii+414. (London: Royal Cancer Hospital (Free), 1943.) 16s.

Twenty-seven authors contribute to this symposium, which will be welcomed by all who have to deal with any aspect of cancer. The papers, some of which are highly technical, are reprinted from many journals and form four main groups: three of general clinical interest; four on radiation therapy; eight on calculations and physical measurements of radiation; eighteen on experimental research, and a review of the world literature 1938–1939 on chemical compounds as carcinogenic agents. The latter paper, by Profs. Cook and Kennaway, follows an earlier review on the same subject and is a masterly piece of work, including a bibliography of some five hundred new references. About half the volume is concerned with the synthesis and testing of chemical carcinogens and growth inhibitors. It is not yet certain that any of these substances are directly related to human cancer other than industrial cancer. A careful perusal of the results shows that many new facts could not have been established by studying only the earliest and best-known carcinogenic hydrocarbons. To the reviewer, the most interesting new experiments are those dealing with growth-inhibiting hydrocarbons that are not necessarily carcinogenic; with carcinogens that act on remote organs as well as locally; with those that show the need for more than one kind of biological test before a substance can be regarded as non-carcinogenic; and, particularly, with the extraction from human livers (not necessarily from cancer subjects) of unidentified carcinogens.

The scientific world owes much to this team and to the guiding influence of Prof. Kennaway, who was the first to prove that cancer could be induced by a hydrocarbon. P. R. Peacock.

ROAD ACCIDENTS AND ROAD STRUCTURE

By W. W. DAVIES

According to recently published information, 40,000 people were killed on the roads in the United States in 1941 and the cost of all road accidents during the same period amounted to little short of £500,000,000[1]. Comparable figures for Great Britain are not available, but the records of past years speak for themselves. In the ten years preceding 1940, 69,781 people lost their lives in road accidents and about 2¼ million people were injured. The most conservative estimate shows that the average cost of these accidents to the community, together with that of the much larger number of accidents involving damage, but not death or injury, could not have been less than £50,000,000 a year.

The figures for the two decades prior to the War show that the number of accidents was roughly proportional to the total number of vehicles using the highways (Fig. 1). In the case of the United States, up to 1938 the accident curve reflects quite remarkably the curve of the number of vehicles. The graph for Great Britain shows less faithful correlation, due to the increase in accidents in the 'bad' years 1931–34; but there is no significant break in the general relationship. The accident/vehicle ratio was 0·082 in 1925, and after reaching a maximum value of 0·098 in 1934, was again 0·082 in 1938.

There seems little doubt that the number of vehicles in Great Britain will increase two- or three-fold in the twenty-five years following the War, and that *unless novel methods of prevention are introduced*, the country will be faced with an annual casualty roll mounting steadily to some 500,000, representing an economic loss of the order of £100,000,000 a year. Road accidents, in fact, are a liability that the nation can ill afford at the best of times, much less with a man-power depleted by the ravages of war. Humanitarian motives apart, it is clear that on grounds of economy alone, the spending of very large sums of money on prevention will be fully justified.

The causes of road accidents are so numerous and complex as to defy all but the most detailed analysis[2]. As motor-vehicles are involved in some 85 per cent of the accidents, however, it is a reasonable simplification to say that the essence of the road accident problem is to find a way of neutralizing the 'accident-potential' of the motor-vehicle. Broadly speaking, this may be achieved in three ways:

(*a*) By reducing the lethal effect of the vehicle (for example, by automatic speed-control or by guard devices).

(*b*) By inducing greater caution and skill in the road-user by means of legal restrictions and penalties, and through education and propaganda.

(*c*) By improving the road structure (for example, by segregation, better surfaces, etc.).

Opportunities to reduce the lethal power of the vehicle are very limited; they probably do not go beyond minor improvements in steering and braking, and in providing a wider and less interrupted angle of view for the driver. A large proportion of accidents are stated to occur at speeds between 10 and 20 m.p.h., and although these figures may underestimate the facts, it would scarcely be practicable to reduce the speed-capacity of vehicles to the safety level (wherever

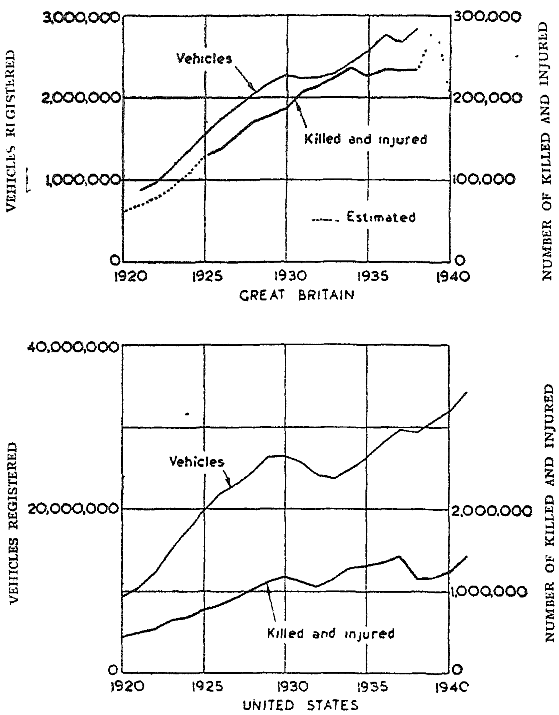

Fig. 1. VEHICLES AND ROAD ACCIDENTS IN GREAT BRITAIN AND THE UNITED STATES.

this may be) without enormously reducing the utility of road transport.

To 'improve' the road-user is at first sight an attractive proposition, and there is no doubt that a great deal can be, and will be, done to educate and restrain all classes of user. As the road structure is the theme of this article, the temptation to enlarge on this aspect of road safety must be resisted. We may note in passing, however, that all the campaigns and efforts on behalf of road safety of the past twenty years, although they have undoubtedly had beneficial effects, have notably failed, as the curves in Fig. 1 show, to reduce the overall accident/vehicle ratio below its value in 1925. Moreover, the reformer is handicapped by the nature of the weapons at his command; restrictive measures are unpopular because in most cases they have to be applied to the just as well as to the unjust; punishments cannot easily be devised which do not harm innocent people; and propaganda has to fulfil the almost impossible condition that it must be persistent without losing its novelty. While, therefore, improvement of the road-user must be regarded as one of the major objectives of the immediate post-war attack on road accidents, it would be unwise to anticipate sensational successes or to rely upon it to maintain a lasting effect.

Effect of the Road Structure

To consider now the restricted accident field imposed by the title of this article: What can be expected from improvement of the road structure?

The answer to this question in official statistics is, to say the least of it, discouraging; for "road conditions" (including the weather) are said to be the "sole or main cause" in no more than 5 or 6 per cent of the accidents. These statistics, however, are based on reports prepared by the police, whose primary job

is not to dissect the road accident problem but to assign responsibility; and it is fully realized that these do not represent the real part played by the road structure. For more illuminating evidence we must turn to authorities who are responsible for road conditions, and who have therefore made a special study of the effect of these conditions on road accidents.

The best-known example in Great Britain of the effect of the road structure is afforded by the experiments conducted by the County Surveyor of Oxford before the War in co-operation with the Ministry of Transport[3]. To test certain conclusions that had been reached by the County Surveyor, fifty-eight junctions on rural roads within the county were improved to the standard recommended in the Ministry's Memorandum 483 on the layout and construction of roads; and the effect on accidents was observed. In the twenty-one months following the completion of the improvements, there were no fatal accidents; non-fatal accidents involving serious injury were reduced by 79 per cent, and accidents involving minor injury were reduced by 37 per cent.

Another published example of the effect of road conditions in Great Britain is given in a paper read before the National Safety Congress by Lyddon in 1939[4]. The accompanying table, which is quoted from this paper, shows the effect on the frequency of road accidents of certain traffic control measures carried out at road junctions.

EFFECT ON ACCIDENT STATISTICS OF SOME PREVENTATIVE MEASURES AT ROAD JUNCTIONS

Type of improvement	Percentage of cases in which number of accidents		
	decreased	did not change	increased
Roundabouts: provincial	78	3	19
London	62	10	28
Island refuges: provincial	75	18	7
Light signals: provincial	53	9	38
Light signals (including a previous analysis)	47	10	43
'Halt' signs: provincial	76	13	11

While the figures show a reduction in accidents at most of the junctions, it is interesting to note that there was a marked increase in quite a large number of cases. This fact is significant in the light of comments to be made later.

In general, the evidence from the United States suffers from incompleteness of data, but two investigations may be mentioned as showing a fairly reliable trend. The first was concerned with the effect of 'safe-speed' signs (not used in Great Britain) in alleviating accidents on curves. The signs were erected in 1939 on a 95-mile stretch of highway in Indiana. Records of the accidents during a year before and after the installation showed that despite a 15 per cent increase of traffic, "there were 10 fewer fatalities and 12 fewer persons injured, 36 fewer accidents on curves and approximately $9,000,000 less property damage as a result of the erection of the signs"[5].

The second investigation was concerned with the effect of the colour of the road surface on night-driving hazards of a street in Philadelphia[6]. Here, for reasons not connected with safety, the tone of the road surface was changed from light to dark without any corresponding alterations in the character of the street-lighting. Examination of accident statistics showed that, whereas in six winter months preceding the change 232 accidents had occurred during daylight and 182 at night, in the corresponding period after the change the ratio was reversed, 172 accidents occurring in daylight and 211 at night.

The Case of a London Street

A very striking example of the effect of the road structure on the incidence of road accidents occurred in the course of an investigation, undertaken by the Road Research Laboratory as part of the programme of the Road Research Board, on the use of surface-dressings to reduce the slipperiness of certain types of paving in London. The Board being concerned with research on road materials and methods of construction, the tests were devised in the first place to examine the efficacy of a certain type of surface-dressing in terms of its durability and resistance to skidding. As the ultimate object of such treatments is to increase road safety, it was decided later to attempt to link-up the improvement made in the road surface with its effect on road accidents, and police records of all fatal, non-fatal and damage accidents involving vehicles before and after the improvement were examined. About a year earlier, island refuges had been installed on the same stretch of road, so the period of the statistics was extended to cover this feature also. Traffic records over the period of the review were not available; but there were no indications of any appreciable variation either of traffic density or of any other factor that might have affected the accident ratio.

The results of the inquiry are indicated diagrammatically[7] in Fig. 2, which shows the incidence of accidents between November 8 and February 7 in the three successive years during which the changes in the road conditions were made. Referring to the two areas under observation (hatched on the bottom diagram), the main conclusions were as follows:

(1) In the three months following the installation of the island refuges, a measure specifically intended to reduce accidents, 63 accidents occurred, compared with 24 in the corresponding period of the previous year.

(2) After the sections had been surface-dressed, the number of accidents on them fell from 63 to 4. In the same period there was a considerable increase in the number of accidents on other stretches of the road.

(3) Although the surface-dressing treatment had served only to reduce the slipperiness of the road surface, the proportional reduction of accidents (94 per cent) was far greater than the proportion of accidents previously attributed in police reports to skidding.

(4) Although measurements showed that the treatment had reduced the slipperiness of the surface only at low speeds (up to 10 m.p.h.), the treatment practically eliminated accidents on the lengths treated.

(5) Assuming the average cost of the accidents to be £10 per accident (a conservative figure) the initial outlay on the treatment was recovered in less than two months by savings on accidents. Assuming the surface-dressing would require renewal after two years, the savings on accidents would represent a 'dividend' in this period of 1,500 per cent.

A notable feature of these results is their unexpectedness. The installing of island refuges actually caused a serious increase in the number of accidents; while the surface-dressings, although having such a

limited effect on the slipperiness of the surface, reduced the accidents to negligible proportions. It is equally noteworthy that the police reports, because of the particular viewpoint from which such reports are prepared, failed to give proper emphasis to the influence of road conditions on the accident ratio.

How Science Can Help

From what has been said, it will be seen that far too little is known of the principles governing road safety and the relationship between traffic and road structure—for the simple reason that no organized and persistent attempt on a sufficient scale has been made to track these principles down. It is true that the police in many areas maintain accident maps; and by concentrating road improvements on the 'black-spots', local authorities are often able to secure a substantial reduction of accidents: but little attempt is made to collect the supporting data by means of which a local success might be translated into a general relationship. 'Belisha beacons' marking pedestrian crossings have been installed in the towns and cities of Great Britain: but who can say with certainty whether they have failed or succeeded in their object? There is much talk of the benefits to be derived from motor roads: but there is not a single piece of reliable evidence to show that motor roads would effect an overall reduction in the number of accidents.

Those are but a few of many examples of our failure to study the fundamental causes of road safety. To borrow a popular metaphor, our method of attacking the problem has been tactical in scope: its objectives have been limited and immediate, its methods simple and its instruments ready-to-hand. There is a growing realization that this is not enough, and that it must be backed up without delay by a strategic attack having fundamental and far-reaching objectives, using the precise methods and instruments of science, and envisaging remedies that may not be immediately applicable. Such a step, in fact, was envisaged by the Alness Committee in its recommendation that a Road Safety Research Board should be set up, so far as possible as an independent body but closely in touch with the various authorities concerned with road safety. The functions of the Board would be to conduct researches and to make recommendations. A Road Safety Research Committee has already been set up in the Union of South Africa.

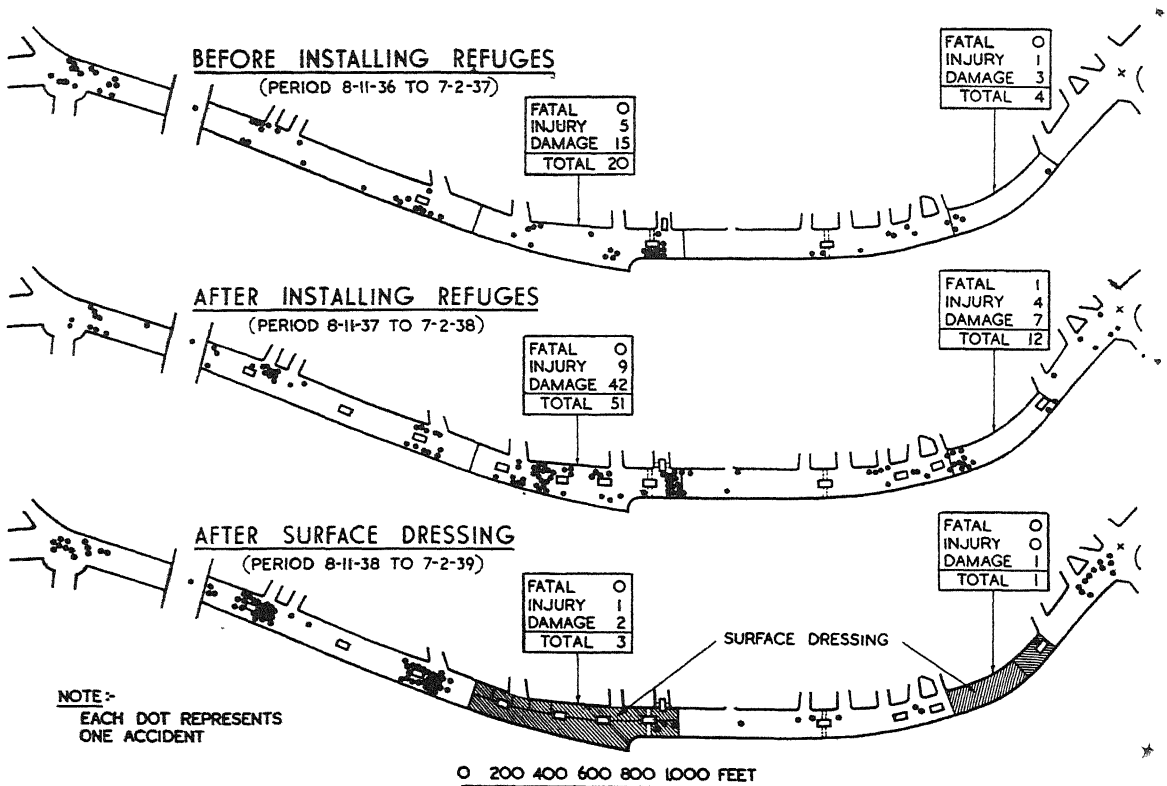

FIG. 2. RELATION OF ACCIDENTS TO ROAD CONDITIONS ON A LONDON STREET.

The field of investigation is obviously a wide one, and it embraces problems associated with the vehicle and the road user as well as with the road structure. Space permits only a brief reference to two or three aspects that concern road structure.

As there are 200,000 accidents yearly (omitting the large number of 'damage' accidents), and at least twenty-five major variables affecting the road structure alone, it is clear that the conditions for investigation are difficult and that a great deal will depend upon a proper use of statistical analysis. But contrary to general practice in the past, the statistics will have to be collected by trained observers, they must include not a few but many factors relating to the road, and they must aim at elucidating facts rather than apportioning blame. Since the accident/traffic ratio, rather than the actual number of accidents, is clearly of basic importance in a scientific

inquiry, parallel statistics relating to the type and density of traffic will also be required. The task is a formidable one; but it can no doubt be reduced to manageable proportions by sampling and by the use of standardized methods.

The scientific worker in partnership with the road engineer will also require a 'practical laboratory' in which the conclusions reached by theory and experiment can be tried out under normal working conditions and checked statistically. The area, or areas, might well be selected from those set apart for the statistical inquiry; and it would be necessary not only to avoid publicity but even to go to considerable trouble to conceal the experimental character of the site from the road user. As the behaviour of drivers is often conditioned by events in the recent past (for example, a 'narrow squeak' or a passing glimpse of the results of an accident) a careful watch would also have to be kept for possible 'edge effects'. Under properly controlled conditions, however, the true, as distinct from the local or temporary effects of modifications in the road structure, would in course of time be ascertained.

Finally, there is a large field for purely experimental research, in the laboratory as well as on the road. Perhaps the most important part of this work would be concerned with the relationship between the road structure and the movement or 'flow' of vehicular traffic. It is a curious thing that in spite of a quarter of a century of experience of modern road construction, very little is known of this relationship, and methods of design are still empirical. Making full allowance for the complications introduced by the presence of the human factor, it seems certain that definable laws govern the movement of vehicular traffic along the channel of the highway, and that they are dependent on the alignment and width of the carriage-way and the incidence of such intermittent elements as road junctions and traffic signs. It is the business of research to study these factors experimentally. By doing so, not only will valuable contributions be made to the solution of the problems of road safety, but also the information will help materially to reduce the overall cost of road transport to the community.

As O'Gorman, who has done much to direct public attention to the problem of road accidents, has said[8]: "What we want, what we lack and what we must have are measurements scientifically correlated, and analysed by competent persons".

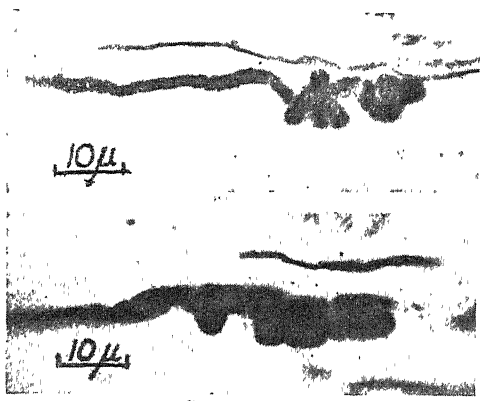
CONTRACTION, TURGOR AND THE CYTOSKELETON OF NERVE FIBRES

By J. Z. YOUNG

Department of Zoology and Comparative Anatomy, Oxford

A STRETCH of nerve fibre which has been cut off from its cell body degenerates and disappears. There must, therefore, be some influence emanating from the cell body and nucleus which normally maintains the integrity of the axon. Two facts which throw light on the nature of this influence are that (1) during degeneration the isolated portion contracts and forms folds and spirals; (2) the central portion swells as if under the influence of a turgor pressure.



Figs. 1 and 2*. SPIRALS IMMEDIATELY BELOW A CUT MADE 48 HOURS PREVIOUSLY.

The contraction is shown most markedly in the region immediately distal to the cut, where the fibres contract back, often into quite tight folds and coils (Figs. 1 and 2). The more distant regions of the fibres remain intact for about two days (in a mammal) and then break up into granules, falling into loose spirals as they do so (Fig. 3). This contraction is presumably a manifestation of the process of disorientation of longitudinally arranged protein particles, the presence of which is shown by many other indications. The axoplasm shows a visible longitudinal fibrosity (the 'neurofibrils'), and birefringence studies indicate that part at least of the protein exists as micelles showing form and intrinsic anisotropy[1]. Electron microscopy of extruded squid axoplasm shows the presence of fibrils of all sizes from 15 mμ upwards[2]; distilled water or formalin coagulate the smaller particles into larger fibres[3]. The small amount of evidence available about the proteins of the axoplasm shows them to contain a complex resembling a nucleo-protein, from which a basic constituent like a histone or protamine can be split off[1].

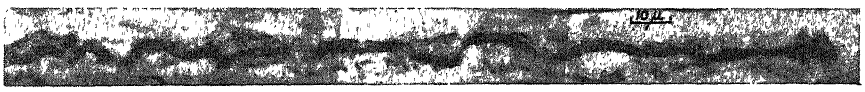


Fig. 3. MORE DISTANT PORTION OF AXON 3½ DAYS AFTER CUTTING.

It is therefore evident that the axoplasm contains orientated molecules. In the intact fibre these are

* All figures are of sections of rabbit's nerve stained by Bodian's method. They are arranged as if the cell bodies lay to the right.

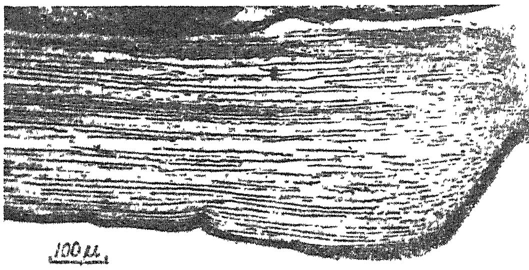

Fig. 4. PERIPHERAL END OF NERVE CUT FIVE MINUTES AFTER ALCOHOL HAD BEEN POURED AROUND IT.

somehow held in the extended condition, which is not the most probable one, so that when the constraining force is removed the disorientation is shown by the contraction, folding, disappearance of birefringence and break-up of the fibrous organization into granules. It is interesting that agents such as dehydration or heat accentuate the contraction. Very marked spirals are seen at the ends of nerves which have been immersed in alcohol just before cutting (Fig. 4). Schmitt and Wade[4] have shown that the shortening of nerves when heated is due to contraction of the axons and not of the supporting tissue.

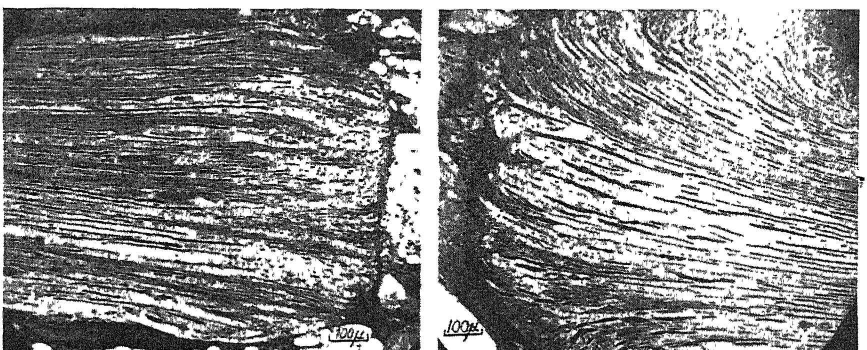
Since, when a piece of nerve is isolated, there is a disorientation of previously well-arranged particles, it may be suggested that the influence of the nucleus and cell body is to maintain this organization. Parker[5] has already suggested a connexion between the 'neurofibrils' and the 'trophic impulse' in an axon. A clue as to how the transmission may be effected is provided by the fact that the material in the central stump is under pressure. On the second day after cutting, the central ends of the nerve fibres are swollen and reach to the open ends of the endoneurial tubes in which they lie (Fig. 5). The peripheral ends, on the other hand, lie some tenth of a millimetre back from the cut surface and are little swollen. During the succeeding days the material of the central end flows out from the tube, forming one or several regenerating strands. These phenomena seem to show that there is a turgor pressure within the nerve fibre which must be transmitted from the cell body, since it is absent from the peripheral stump, although this is symmetrical with the central one except at the ends. The whole central stump is visibly more swollen than the peripheral[6,7], probably largely as a result of this intra-axonic pressure, although, as Weiss suggests, the swelling may be partly due to the accumulation of fluid between the nerve fibres, as a result of a centrifugal flow in the endoneurial lymphatic spaces.

Further evidence that there is a pressure and movement within the nerve fibres is the observation of Gutmann and Sanders[8] that during regeneration the diameter of fibres in the central stump decreases, while that of the fibres developing from them is increasing.

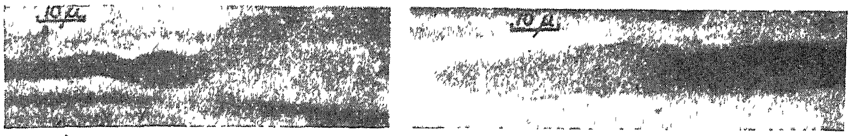
That the material of the axons is a fluid, or at least is thixotropic, is shown by the fact that it can flow freely and quickly from the ends of the large axons of Cephalopods[3], and by the movements which Speidel[9] has seen within it. We can therefore imagine the transmission of a turgor pressure along it, and this may well be important for several aspects of its functioning, including the maintenance of the orientation of its proteins. Studies on virus proteins and other materials[10,11] have shown that there are long-range forces capable of maintaining needle-like particles parallel to each other. Orientation in such solutions is produced by flowing and "the action of neighbouring surfaces, for example, in narrow tubes". Waugh[12] finds that the globular molecules of insulin may also form fibrous aggregates under mechanical stress.

The pressure could scarcely produce the orientation of the proteins originally, unless there is a definite continuous movement within the axoplasm. But the original orientation is produced during development, probably by the relatively rapid flowing which certainly occurs at that time. The influence of the cell body is to *maintain* the orientation, and it seems not impossible that it does this by the pressure which it produces within the axon. Comparison of the central and peripheral tips of the severed fibres certainly shows signs of disorientation in the latter (Figs. 7 and 8). Both may terminate in a lightly staining cap, but in the peripheral stump this contains a tangle of irregularly twisted or spiral threads, whereas the material in the central stump, besides being turgid, is also more orientated.

Of course, the fact that there is a disorientation during degeneration does not prove that the influence of the cell body is exerted directly by the maintenance of molecular orientation. The effect might be produced by a substance diffusing from the cell body which was necessary to maintain the metabolic activities of the fibre, and these in turn for the maintenance of the organization. Such diffusion has often been suggested, though no convincing evidence for such a substance has ever been produced. Hardy[13] considered that diffusion would be too slow, but Howe and Bodian[14] have shown that the virus of poliomyelitis spreads within the axoplasm at a rate of 2·4 mm. per hour; of course, the process need not be simple diffusion. A suggestion of correlation between the organization and the metabolism of a nerve fibre is the fact that isolated nerves which are stimulated become inexcitable sooner, and perhaps degenerate sooner, than those left at rest[15]. Gerard



Figs. 6 and 5. ENDS OF NERVE CUT 33 HR. PREVIOUSLY. IN THE DISTAL STUMP THE FIBRES END SOME WAY BACK AND ARE LITTLE SWOLLEN, WHEREAS THE TURGID ENDS OF THE CENTRAL FIBRES REACH TO THE CUT SURFACE. NOTE THAT THE CENTRAL STUMP AS A WHOLE IS OF MUCH GREATER DIAMETER.



Figs. 6 and 7. Central and distal ends of fibres from a nerve cut 48 hr previously

interprets this effect as due to the exhaustion of a supply of material normally diffusing from the cell body.

Hardy[13,16] suggested that organization within a cell might depend on an ordered arrangement of molecules originating at an interface and transmitted through quite large distances. Danielli[17] has a similar thought, that in muscle fibres the resting potential may orientate the outer molecules of the fibres, which in turn orientate those within. A similar relation might well obtain in nerve fibres, and would be consistent with the contraction and spiralling which are here discussed. However, since we know that the resting potential is maintained, at least for a time, in an isolated stretch of nerve, it cannot be regarded as an influence emanating directly from the cell body. The turgor pressure seems to be the only such influence for which there is some evidence, and it therefore merits serious consideration as the agent responsible for maintaining the organization.

It is even possible to suggest how the nucleus plays a part in maintaining this pressure. Gersh and Bodian[18] have confirmed the view of Caspersson[19] that the basophil Nissl granules contain nucleotides. After the application of ribonuclease, nerve cells lose the characteristic nucleic acid ultra-violet absorption band at 2600 A. Moreover, this band also becomes much less marked in cells undergoing the 'chromatolysis' which follows section of their axon. Gersh and Bodian suggest that after severance of the axon the intra-cellular ribonuclease breaks up the nucleotides, allowing the nucleoproteins of the Nissl substance to depolymerize and hence to produce the increased intra-cellular osmotic pressure which gives the turgid appearance to these cells and leads to the lateral displacement of the nucleus. It may be suggested that normally some such process goes on continually, and that it is the 'function' of the Nissl substance to provide the material the break-up of which increases the intra-cellular pressure necessary to maintain the organization of such long cells. This would explain the occurrence of such large amounts of extra-nuclear nucleo-proteins in these very large cells. It has often been suggested that after chromatolysis the Nissl substance is re-formed from the nucleus, and this has been confirmed by Hyden[20]. Possibly in this way the nucleus maintains a pressure within all cells, and hence perhaps the orientation of a 'cyto-skeleton' of proteins. There have been many indications in recent years of the importance of such a 'cytoskeleton'[21,22,23], but we lack definite information about its connexion with either metabolism or the control exercised by the nucleus over the cell.

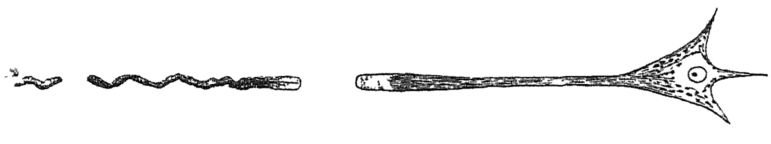


Fig. 9. Diagram to show appearances in central and distal portions of a nerve fibre during the days following section.

No doubt these relations will prove to be much more complex than are here suggested. But at least we have two significant and probably connected facts (summarized in Fig. 9): (1) there is a turgor pressure transmitted from the nerve cell body, and (2) degeneration of severed parts is accompanied by the disorientation of a protein framework.

OBITUARIES

Dr. F. D. Chattaway, F.R.S.

The death of Dr. F. D. Chattaway, which took place at Torquay on January 26, severs another of the few remaining links between organic chemistry in Great Britain and the great school of the subject built up by von Baeyer at Munich.

Frederick Daniel Chattaway was born on November 9, 1860, at Foleshill, Warwickshire, and was the eldest of the five children of Daniel Clarke Chattaway and Eliza Ann Adcock. His father was a ribbon and trimming manufacturer in Coventry, and the collapse of this trade which followed the treaty with France in 1870 caused the family a very severe loss of income. As a consequence, Chattaway's scientific education was achieved almost entirely by means of scholarships; while as a further consequence he thereby gained an experience of universities and colleges wider than falls to the lot of most men. He received his early education at a school kept by a Nonconformist Minister, the Rev. J. L. Withers, who fostered his taste for natural science—a taste which had already been stimulated by his grandfather. His scientific education proper began at Mason College, Birmingham, where he was a pupil of Sir William Tilden. From there he went to University College, Aberystwyth, for two years, and then won a scholarship to Christ Church, Oxford, where his tutor was A. G. Vernon Harcourt. He took his degree with first-

class honours in chemistry in 1891, and then proceeded to Munich to work under von Baeyer and Bamberger.

On his return to England, Chattaway became a demonstrator in the Chemical Department of St. Bartholomew's Hospital Medical School, being appointed head of the Department when Dr. Russell retired. He left St. Bartholomew's in 1905 and again went abroad, this time to Heidelberg, where he studied under Bredig, and to Utrecht to work with Ernst Cohen. During this period, while he was in Holland, he was elected into the Royal Society.

Back in England he settled in Oxford, where in 1909 he took over from Cronshaw the chemistry teaching at Queen's, of which College he became in due course fellow, tutor and praelector in chemistry. He retired from teaching in 1935, remaining, however, a supernumerary fellow of Queen's until his death.

Chattaway was once described by an Oxford colleague as a "true-blue organic chemist", and the description fitted. Although his sojourn on the Continent from 1905 onwards was the result of his desire to acquaint himself with the then new subject of physical chemistry, he never really took to, or sympathized with, physical methods as applied to organic chemistry, preferring always the "beautiful crystalline body" which could be handled and investigated directly, and so with a greater feeling of reality. It was, in fact, in the production of such materials that a large part of his practical skill lay: few men excelled him in the ability to produce pure crystals from the most unpromising tars.

Within the realm of organic chemistry as he understood it, all was grist to his mill. Always his interest was in the way substances reacted together, and in the elucidation of the constitution of any hitherto undescribed products of a reaction. Here again lay one of his gifts; for he had a knack of choosing the correct alternative for synthesis, where doubt was still possible after degradation experiments, in a way reminiscent of Medicus's famous pronouncements on the purines. But he was no mere 'paper chemist': in the laboratory his industry was prodigious and his enthusiasm unbounded and infectious.

Chattaway's earliest work was done with Bamberger at Munich, and resulted in the determination of the constitution of a number of polynuclear hydrocarbons which occur in minute quantity in the highest boiling fractions of coal tar. His patience and tenacity were early shown in this work, which was both laborious and difficult, by reason of the intractable nature of the materials concerned and the very small quantities available. Later, his interest was caught by nitrogen iodide, and a series of thorough investigations enabled him to settle several hitherto doubtful points in its chemistry. He later prepared and examined exhaustively the properties of a very large number of N-substituted halogen derivatives of acylanilides, and championed with great vigour the view that the change which occurs when they are treated with acids is an intra- and not an inter-molecular change. He then became interested in organic perhalides, particularly those of the diazonium compounds, and in all aspects of the chemistry of hydrazines and hydrazones. He also investigated the nitration of benzil, condensation reactions of azides, many cases of polymorphism, and the stereoisomerism of thioparachloral derivatives, while his most recent work on condensation products of chloral and related compounds revealed a ready means of making derivatives of the benzdioxin ring system.

Chattaway's delight in the *practice* of organic chemistry was never dimmed and he only gave up the long hours of work in the laboratory (and then grudgingly and regretfully) when advancing age and circumstances left him no alternative. A small army of pupils owes to him a training in the methods of organic chemistry which could not have been excelled.

Dr. Chattaway married in 1894 Elizabeth Bettney, second daughter of Thomas Bettney, of Handsworth, Birmingham, who, with a daughter, now survives him. Their only son, a scholar both of Eton and of Christ Church, was killed at Thiepval in 1916.

G. D. PARKES.

Prof. Alfred Stansfield

THE announcement of the death on February 5 at the age of seventy-two of Prof. Alfred Stansfield, for thirty-five years Birks professor of metallurgy at McGill University, Montreal, has recalled to many of his friends and associates the outstanding contributions made by him to the progress of physical metallurgy in Great Britain while collaborating with Sir William Chandler Roberts-Austen at the Royal Mint and also at the Royal School of Mines.

To Stansfield was due in no small measure the actual experimental work and the improved means of pyrometric measurement (including the 'null' and 'differential' methods) which constituted such remarkable features of the Third, Fourth and Fifth Reports made by Robert-Austen to the Alloys Research Committee of the Institution of Mechanical Engineers, in 1895, 1897 and 1899 respectively. An important appendix to the Third Report, on "The Pyrometric Examination of Alloys of Copper and Tin", appeared under Stansfield's name. Its importance at that time can scarcely be over-estimated. Not only did it represent the first recorded attempt to give as 'freezing-point curves' an explanation of the copper-tin series as a whole, but it also marks the beginning of all investigations which have since been made in correlating the physical and mechanical properties of alloys with their equilibrium curves. Stansfield, in fact, a few years later, himself suggested the adoption of the term 'equilibrium curve' for metallic alloys, a term which had hitherto been restricted to the consideration of fused salts and saline solutions.

Stansfield's most striking and convincing contributions to physical metallurgy, however, were those by which he participated in the discussions in the late 90's on the "Solution Theory of Carburised Iron". Of the two papers by him which appear in the *Journal of the Iron and Steel Institute*, 1899 and 1900, it can well be said that these constituted a remarkably clear enunciation of the problems involved in a proper understanding of the relations between carbon and iron within the ranges covered by steel and cast iron. The latter of these two papers was presented and discussed jointly with the well-known contribution by Bakhuis-Roozeboom on "Iron and Steel from the point of view of the Phase Doctrine". Stansfield expressly set out to dispel the tendency to regard the solution theory as being, in a sense, opposed to, or as supplanting, the older allotropic theory. His paper, he hoped, would effectually dissipate such an error by showing how entirely the solution theory of the relations of carbon and iron involves the allotropic changes with which the distinguished name of Osmond is inseparably connected. Roberts-Austen, who was at that time president of the Iron

and Steel Institute, commended Stansfield's work in terms which now appear as being prophetic. He said: "He considered Dr. Stansfield's communication to be about as important as any that could well be made to the Institute. Its full significance might not be understood for months or even for years but it did afford a scientific basis on which the theories and practice relating to the metallurgy of iron might be built up".

Prof. Stansfield's subsequent work in Canada included, among other important matters, notable contributions to the technology of electric furnaces and of their application to electric smelting. This work has received wide recognition and is probably more familiar to those of later generations than his earlier work in Great Britain to which this note is intended more particularly to direct attention.

S. W. Smith.

Prof. James Young, O.B.E.

James Young, who retired from the professorship of science at the Royal Military Academy, Woolwich, in 1925, died on December 2, 1943; he was born in Ulster in 1862.

Young joined the Royal Military Academy in 1889 as instructor in chemistry. When war started in 1914, the authorities had ordered that all non-military subjects should be shut down; but Young had no difficulty in persuading a sympathetic commandant that science was a necessity, not a luxury, and the order was quietly ignored. With the small time available in a much shortened course, Young did great work, which was rewarded by the O.B.E.

When Young came to the Royal Military Academy, science there was little but chemistry applied to explosives. The Academy had been early in the field with chemistry. It was first taught there in 1789, and one of its teachers for thirty years had been the great Faraday himself. Electricity came in 1893, and Young wrote an Army handbook on that subject later on.

Young did little research, but great teaching work for the Army, and it was as unobtrusive as it was useful. He was far-sighted in his ideas of science in warfare. When wireless telegraphy was in its infancy, he put it in the curriculum, predicting its great future in the field. Also, within a few days of the first German gas attack, he was giving lectures on poison gas which became famous in the Army, and predicting that mustard gas would be the most effective.

Young was rather a recluse, and perhaps rather too gentle with his high-spirited students, though he earned their respect from his clear and original lectures, and is remembered with affection by many who are now officers of high rank. Particularly well remembered are his lectures on explosives, with their terrifying bangs, by which he made everyone realize how safe explosives are when handled with understanding; he was highly successful in giving his students the confidence due to knowledge. No one ever had an accident under his care.

NEWS and VIEWS

Science and Industry in Great Britain

A series of meetings on science and industry has been arranged by the Manchester Chamber of Commerce. The first of these meetings, on March 3, was addressed by Lord Riverdale on "Research and Industry: the Need, the Ways and the Means"; the second, on March 16, by Dr. A. P. M. Fleming on "Research Workers: their Education, and their Place in Industry". At subsequent meetings on March 31 and April 20, the speakers will be, respectively, Dr. Andrew McCance on "The Application of Research" and Sir Edward Appleton on "Fundamental Research: its Practical Importance". The meetings, admission to which is by ticket, are being held in the Houldsworth Hall, Deansgate, at 11.30 a.m.

At the first of these meetings, which was attended by several hundred business men, Lord Riverdale gave an outline of the work of the Department of Scientific and Industrial Research, and more particularly of the activities of the research associations in Great Britain, which at least hinted that when publication of the annual reports of the Department is resumed, it will be found that the research association movement has gained new vitality. Lord Riverdale gave a list of twenty-two existing associations and stated that several others are in process of formation. The provision of means and the formation of research associations, however, are not enough. Until individual firms use these means and become imbued with a full appreciation of scientific research and translate it into highest quality products, full benefit to firms and the community has not been achieved. Much remains to be done, especially in those industries containing many small units. Lord Riverdale is not satisfied that the Department can 'put over' the results of its research sufficiently dramatically, or that members of the associations really take an interest in it; the Department is now creating a public relations officer to meet this need. He also thinks that the question of invention requires further attention. Unless we have an authority with sufficient funds and able staff to watch inventions, see how they react on research in progress here, and make some attempt to introduce them to a concern which will test them effectively as to whether they are not of national importance, there is serious danger that we shall not be able to hold our own. Lord Riverdale also referred to the importance of obsolescence and of allowance being granted by the inland revenue authorities and the Treasury for expenditure on buildings and equipment for research—a matter in which he was strongly supported by Sir Raymond Streat, who also emphasized the implications for industry itself.

Lord Riverdale's address showed that the present outlook of the Advisory Council for Scientific and Industrial Research is in full harmony with that inspired by Lord Balfour and Lord Rutherford. While he did not disguise the dangers ahead and the necessity for Great Britain to increase its visible exports at least another two hundred millions if it is to continue to enjoy imports of the same value as before, he pointed out that, to an ever-increasing extent, the value of British exports must lie in the superior ability of our scientific men and technologists, the

keener enterprise of our industrialists and the higher skill of our workmen. Experience of the War has shown that Great Britain is second to none in the fields of scientific discovery and invention, and industrialists have shown that they are capable of translating the results of research rapidly and efficiently into products required for the successful prosecution of the War. This high quality of research is one of the surest grounds for confidence in our ability to meet successfully the difficult times that lie ahead.

Taxation and Research

REFERENCE has been made in various recent reports on scientific research and industry to the financial aspect in its relation to taxation. Thus the London Chamber of Commerce report (see NATURE, March 11, p. 294) advocates that expenditure on research should be chargeable on revenue. The matter has also been taken up by the Parliamentary and Scientific Committee, which has prepared a memorandum on the subject. This memorandum urges that the Government, in considering its taxation policy, should look to the prospect of benefiting from higher income tax returns when industry, as a result of the development, through research, of new processes and products, is made more profitable. The recommendations, however, are intended to afford a basis for discussion rather than to represent rigid and final views, and in particular the Committee wishes to learn the opinion of the revenue authorities on the practical reactions of its proposals. In general, it is recommended that the law relating to the taxation of profits should be amended so as to recognize the principle that all expenses incurred on research and development are allowable as deductions from taxable profits, with the corollary that receipts from a lease or sale of discoveries should be brought into taxable profits. It is also suggested that an allowance should be made for taxation purposes of a fixed percentage of any capital assets which have been provided solely for research purposes. The Committee also supports suggestions made by representative trade bodies to the Inland Revenue Committee regarding the amortization of business premises and machinery generally. Depreciation rates should be increased so as to include obsolescence, which has become a more important factor than wear and tear.

British Radio Research Institute

THE British Institution of Radio Engineers recommends the formation of a British Radio Research Institute, the functions of which would be the pursuit of basic research of the type that has hitherto suffered restriction owing to its high cost, absence of obvious or immediate practical applications, or the poor prospect of early financial returns. The institute should be financed by industry supplemented by a Government grant of at least equal amount. The work of the institute should be directed by a board representing Governmental authorities, the B.B.C. and the Services, the industry, the British Institution of Radio Engineers, the associated professional institutions and the universities of the Empire. In addition to a permanent scientific staff, the assistance and engagement of extra-mural workers should be arranged in co-operation with industry and the universities.

The advantages to be derived from the proposals are that the advancement of radio and electronic sciences would be freed from the limitations of restricted finance, duplication of original research work, spasmodic trade fluctuations, etc. Competitive private enterprise would be stimulated and the intake of high-grade technical personnel increased. It would remain with private enterprise to develop the practical and industrial applications of the scientific results flowing from the research institute. The pre-war hiatus between industry, the Government and scientific workers would be effectively bridged by the proposed governing board. New knowledge, carrying with it the possibility of new industries, would be continuously sought and be available for the free use of manufacturers to develop practical applications of the scientific principles. The necessity for private research departments would not be reduced; but the availability of undeveloped basic knowledge would give such departments a far greater opportunity for returning a dividend. The application of radio technique to fields other than broadcasting is capable of considerable development, and therefore the potential absorption of labour is considerable.

On the financial side, the contribution of industry to research associations was increasing before the War, and support is now being given to the principle of larger contributions being made in the future. Assuming the turnover to be only £20 million for the radio industry, an allocation of 0·25 per cent would give, with Government assistance, an income comparable with that of other research associations. If subscribing membership is open to all British industrial undertakings in the British Commonwealth which produce, manufacture or use electronic equipment, the income of the research institute would be comparable with the support given to any other association, while at the same time making the field of research inexhaustible. During the War, radio has graduated into a highly important industry. In the post-war era it should be supplying capital goods on a scale equal to many of the older industries; not only should the range and quality of its consumer goods be very different from anything known before, but also essential instruments and devices for other industries must be provided if British scientific and industrial progress is to be maintained. For all this development co-operative research is essential. It is strongly advocated by the Institution that opportunity for participation in the work of the research institute shall be provided for all countries in the British Commonwealth. Such collaboration in research will materially aid development of communications and the prosperity of the entire Empire.

Fuel for Household Use

ON February 18 Mr. J. G. Bennett, addressing the Fuel Luncheon Club in London on "The Future of Coal for Small-Scale Uses", compared raw coal, town's gas and electricity for household space heating. The comparison was based on heat costs incurred in production and distribution and the efficiency in use of gas and electricity when these are produced from coal. The results for all three, with appliances of current type, turned out to be identical —16 per cent of the heating value of the coal. Developments anticipated in appliances were estimated to increase these figures to 45 per cent for coal burnt in open fires, 24 per cent for gas and 33 per cent for electricity. Some may read into these figures the implication that no fuel-saving can be expected from the processing of coal before use. It should, however, be recalled that coal-less countries import

large quantities of coal for carbonization to produce gas and coke. It is unlikely that they are unanimously thriftless. Attention should be paid to the difference in the method of calculation. In the case of coal and electric fires, the resulting heat is usually a product of the raw coal. Gas, however, is derived from the volatile matter only, which is not more than one third of the whole of the coal. Then nearly the whole of the heat cost of processing is charged against this gas, and the end efficiency figure is reduced to one sixth. Even then, the efficiency figure is not less than the figure given for coal and electricity. Unlike, but over and above these, there remains some half-ton of coke available for domestic and industrial uses for which raw coal is unsuitable. At the moment, the Ministry of Fuel and Power is taking advantage of this reserve.

Mr. Bennett mentioned that the financial importance of the by-products of coal is apt to be exaggerated. This is true, but their usefulness should not be depreciated. Tar components amount to about 6 per cent by weight. They are, however, components of smoke and soot. As such, they are better recovered fit for uses which would otherwise necessitate importation of bituminous material. In this connexion it is interesting to take note of the views put forward by Harold Moore, only a fortnight earlier, in a paper read before the Institute of Fuel. This was a plea for a plan to meet the national needs for liquid fuels and organic chemicals. In addition to the development of home refining of petroleum, he considers that the most important feature of the plan should be the extension of coal carbonization. To promote this, he even advocates legislation against burning raw bituminous coal.

Basic English

MR. CHURCHILL announced in the House of Commons on March 9 that the Committee of Ministers on Basic English has submitted a report which has been approved in principle by the Government. So far as concerns the use of Basic English as an auxiliary international language, the Government is impressed with the great advantages which would ensue from its development, not in substitution for established literary languages, but as a supplement thereto, and is taking steps to develop its use as an auxiliary international and administrative language. The British Council will include the teaching of Basic English in addition to its more general activities in promoting the teaching of English for its own sake. Diplomatic and commercial representatives in foreign countries will be asked to do all they can to encourage the spread of Basic English as an auxiliary language. It is also intended to arrange for the translation into Basic English of a wider range than is at present available of literature, scientific, technical and general, both from ordinary English and from foreign languages, and also to increase the supply of manuals of instruction in Basic English. Some Colonial Governments will be invited to issue handbooks in Basic English for Colonial peoples on agriculture, hygiene, etc., and to use it in some administrative instructions. The British Broadcasting Corporation has been asked to consider the use and teaching of Basic English in appropriate oversea programmes. Primary responsibility for questions affecting Basic English and for giving effect to the recommendations of the Committee of Ministers will rest with the Foreign Office through the British Council.

Technology of Tea

DR. E. B. HUGHES, past-president of the Society of Public Analysts and Other Analytical Chemists, was unable to deliver his presidential address when he retired from office last year. Accordingly he delivered it after the annual general meeting of the Society held on March 1, speaking on "The Technology of Tea". Tea-growing areas are not now confined to Asia ; the necessary tropical or subtropical conditions exist elsewhere and tea is now grown extensively in Africa, even so far south as Natal, and also in Russia. In the production of black tea, as distinct from green tea, the main processes are withering, rolling, fermentation and final drying. Withering is a partial natural drying process at as cool a temperature as possible. It dries the leaves to a condition in which they can be rolled and twisted by mechanical action simulating rotatory rubbing between the hands ; this damages the cells, whereupon, possibly as a result of 'disorganized respiration', oxidase of the leaf brings about 'fermentation'. This so-called fermentation is mainly oxidation of polyphenols of the leaf to quinone compounds, which readily produce reddish, copper-coloured condensation products. The polyphenols of the leaf are the so-called tea tannins, but they are not tannins in the ordinary sense, as they are not able to convert hide into leather. The rate of 'fermentation' is highly important ; if too rapid, it gives inferior products, and the greater rate of fermentation, combined with lower quality of leaf grown in hot humid conditions, produces a commoner quality of tea. Indeed, the differences in quality and character between teas from different areas are due mainly to differences in geographical and climatic conditions, rather than to varietal differences in the plants grown. Changes in climatic conditions in the same area may produce much choicer tea at one time than a month earlier or later. It is the practice of blending, dependent on the remarkable skill of the tea taster, that enables the consumer to be supplied with brands of unchanging character. Most good teas, as supplied to the consumer, are blends of more than a dozen lots. Green tea is not subjected to 'fermentation', the enzyme activity being destroyed by heating the leaf (steaming) as soon as possible after plucking, after which the leaf is rolled and 'fired'.

Timber-drying Kilns

LEAFLET No. 30 (August 1943) issued by the Forest Products Research Laboratory, under the auspices of the Department of Scientific and Industrial Research, is on "Observations on the Design of Timber-drying Kilns". The leaflet, which does not pretend to deal in detail with design and construction, may be consulted for the information given on the size of kiln, double-stack pattern, single-stack patterns, heating systems, control instruments, and loading and unloading facilities. It is pointed out that in a well-designed timber-drying kiln provision must be made for (*a*) adequate and uniform air circulation between the rows of timber, (*b*) control of the humidity of the air, and (*c*) control of the air temperature. It is a generally accepted fact that except for a very limited type of drying operation, adequate air movement cannot be obtained except by means of fans, and that as a medium for heating and humidifying the air, steam can scarcely be rivalled. The practice of placing the heating elements and fans above the pile of timber is now fairly common in kiln design,

as this arrangement simplifies the construction and renders it unnecessary to excavate a basement. The propeller or axial-flow type of fan has also proved itself to be rather more adaptable generally to the requirements of timber kilns than has the blower or centrifugal type; the leaflet, therefore, is confined to the overhead-propeller fan types of kiln.

Micronesia and Melanesia

"Island Peoples of the Western Pacific, Micronesia and Melanesia" is the title of another volume in the series of War Background Studies published by the Smithsonian Institution. It is compiled by Herbert W. Krieger, ethnological curator, U.S. National Museum. The work is exactly what is required by anyone following the War in the Pacific at the present time. The Caroline Islands, the Gilbert Islands, the Marshall Islands, Bougainville and the Solomons, New Britain and New Ireland are all mentioned. To begin with, there is a general account of the region and its discovery and early history. This is followed by particular accounts of Micronesia and its islands, and similarly of Melanesia. The description of the native peoples and their customs will prove particularly interesting to many readers. There are throughout a large number of excellent illustrations.

Public Health in Colombia

THE April issue of the *Boletín de la Oficina Sanitaria Panamericana* contains an interesting paper on this subject by Dr. Eduardo Santos, a former president of the Republic of Colombia. He states that in spite of adverse conditions 140 aqueducts, thirty sewers and twenty new hospitals have been constructed in the Republic in the past fifteen or twenty years. More than eight hundred institutions are now devoted to maternity and child welfare, and the prenatal services number at present 126 as compared with 62 in 1937. During this period hospital beds have been increased from 11,422 to 16,322, and forty-five hospitals with a total of 1,500 beds are now under construction. There are at present twenty-five tuberculosis dispensaries as compared with only four in 1937. The yellow-fever campaign is being carried on by the Government in collaboration with the Rockefeller Institute, which has an excellent laboratory at Bogotá devoted to the production of yellow fever vaccine. The campaign against typhus and bartonellosis is continuing. There is practical co-operation between the State and private agencies, such as the Red Cross, the Colombia Anti-Tuberculosis League, the Association for the Care of Lepers and other groups.

The Health of France

THE underground newspaper *Avenir Médical*, as quoted by *The Lancet* of February 12, gives the following account of the effects of food shortage in France. Adolescents are losing weight. Want of strength reduces the competence of adults for their work and favours accidents. Hypotension and anæmia are common. Bone decalcification and rickets are seen as in the regions invaded in 1914–18. 'War amenorrhœa' is prevalent in girls and young women. Famine œdema is becoming increasingly prevalent in private and hospital practice. Tuberculosis has risen by at least 20–30 per cent and assumes malignant forms which are rapidly fatal, especially in young people. Pregnant women being inadequately nourished bear underweight infants with a growing proportion of stillbirths.

Red Blood Cells as Wound Dressings

AN annotation in the *Lancet* (252, Feb. 19, 1944) directs attention to experiments by J. J. Moorhead and L. J. Unger (*Amer. J. Surgery*, 59, 104; 1943) on the application of pooled human erythrocytes, collected and stored aseptically, to wounds. The red cells form a gelatinous mass which dries over the wound, and it is claimed that sepsis subsides under this, while healthy granulations develop. T. H. Seldon and H. H. Young (*Proc. Mayo Clin.*, 18, 385; 1943) have experimented with a dried and powdered concentrate of red cells applied once or twice daily. In some cases this application smelt noticeably; in others it produced severe burning pain and was discontinued. In three cases it gave good results. These authors think that the method deserves further investigation and suggest that bovine erythrocytes might be tried.

An Astronomical Paradox

SCIENCE SERVICE has directed attention to an investigation by Dr. Otto Struve, director of Yerkes Observatory, of 48 Libræ, which "presents a notable paradox". This star reveals the characteristics of a super-giant and also of a main-sequence star. At wave-lengths longer than 3,650 A., a main-sequence *B*-type star is suggested; but at shorter wave-lengths the spectrum resembles a super-giant *A*-type star. During the last ten to twenty years, strong metallic absorption lines have developed. Some spectral lines arising in the gaseous shell surrounding the star are sharp and strong, while others are diffuse and weaker. On the whole, the observations indicate stratification in the tenuous shell surrounding the star. The outside layers are rotating slowly while the inner layers have a much higher speed of rotation, and at times they seem to be contracting and expanding. It is pointed out that there is a certain amount of resemblance between the shell surrounding this star and that observed in 1940 surrounding Pleione, but the peculiarities in 48 Libræ are more difficult to explain than they were in Pleione.

Announcements

PROF. W. H. PEARSALL, F.R.S., professor of botany in the University of Sheffield, has been appointed Quain professor of botany in University College, London.

MR. WALTER FITZGERALD, senior lecturer in geography in the University of Manchester, has been appointed professor of geography in the University in succession to Prof. H. J. Fleure, who retires next September.

DR. OTTO STRUVE, director of the Yerkes and the McDonald Observatories, has been awarded the Gold Medal of the Royal Astronomical Society for his work on the observation and interpretation of the spectra of stars and nebulæ.

PROF. C. H. BEST, professor of physiology in the University of Toronto, and Mr. T. Whittemore, archæologist, have been elected members of the Athenæum under the rule for special elections.

AT the annual general meeting of the Society of Public Analysts and Other Analytical Chemists, held on March 1, the following officers were elected: *President:* Mr. S. Ernest Melling; *Hon. Treasurer:* Mr. George Taylor; *Hon. Secretary:* Mr. Lewis Eynon.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Ground and Cloud Scatter of Electromagnetic Radiation

In former communications, the scattered echoes observed with high-power pulses have been described[1,2]. On a frequency above the vertical-incidence critical frequency there are normally short-lived echoes produced by direct scatter from ionic clouds in region E, and a patch of long-delayed diffuse echoes which has been assumed to be produced by energy which has been reflected obliquely from region F and scattered on its way down to the ground.

Although the rapid reduction in amplitude with increase of frequency suggests that the long-distance scatter is produced by the clouds in region E, it has been difficult to prove that the scatter is not, in fact, at the ground. Using the known theory of oblique transmission, it is possible to calculate the shortest possible delay-time from the $h'f$ curve on either assumption as to the origin of scatter. The difference is not large, but recent experiments in which both have been simultaneously observed have definitely shown that cloud-scatter is responsible.

The first experiments were made using a fixed frequency of 8·8 Mc./s. A typical record of the observed variation of delay-time (in units of kilometres of equivalent height) is shown in Fig. 1, together with the calculated values.

It has since been made possible to vary the frequency of the transmitter, so that the equivalent of an $h'f$ curve is possible. A typical example is shown in Fig. 2.

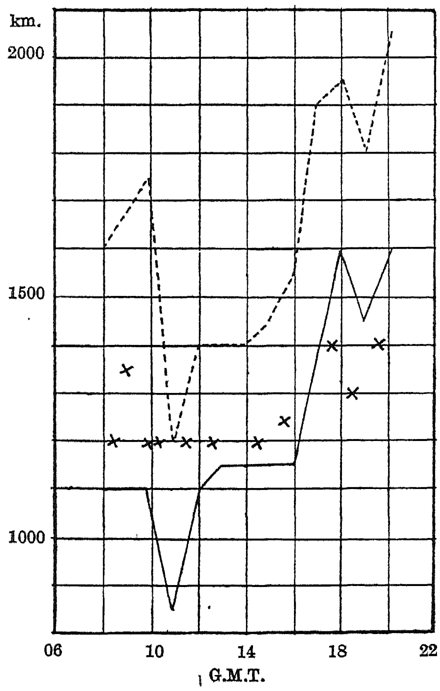

Fig. 1. Scatter delay on 8·8 Mc./s., Oct. 3, 1943. ×, Observed scatter delays; —, calculated delay for cloud scatter; - - -, calculated delay for ground scatter.

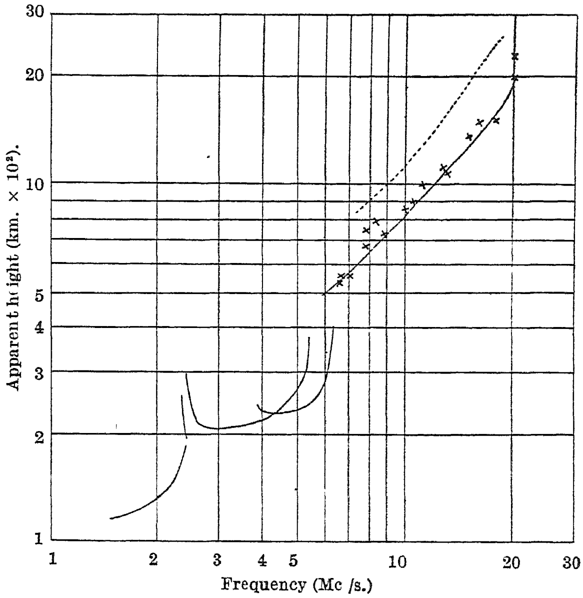

Fig. 2. Scatter $h'f$ curve, 1110–1123 G.M.T., Jan. 4, 1944. ×, Observed scatter delays; —, calculated delay for cloud scatter; - - -, calculated delay for ground scatter.

It will be observed that in both cases the agreement with calculated values shows that the scatter is in fact from the ionic clouds, and the original theory is entirely vindicated. It is not proved that ground-scatter does not exist, because it would be mixed in with the cloud-scatter from lower-angle transmission; but the fact that there is no noticeable increase of amplitude at the delay corresponding to the ground-scatter shows that the cloud-scatter is predominant. The cloud-scatter will be less at higher frequencies, so that eventually the ground-scatter will predominate; but this is not likely to be the case until frequencies greater than about 30 Mc./s. are used, where ionic scatter becomes unimportant because of the lack of F-region transmission.

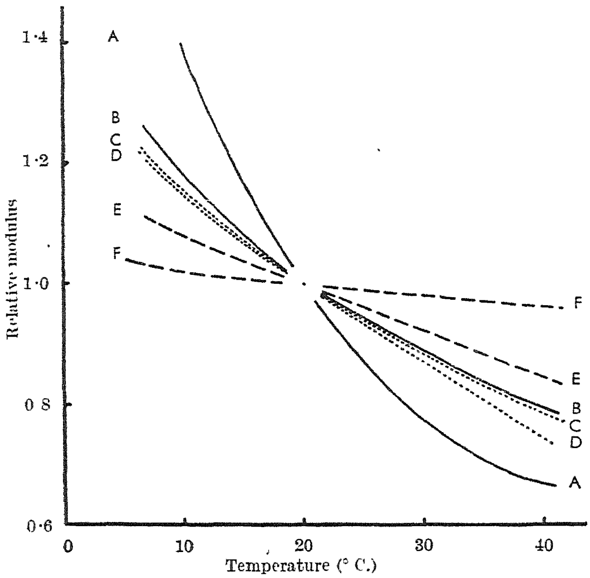
Effect of Temperature upon the Mechanical Properties of Rubber-like Materials

In the course of investigations into the mechanical properties of natural and synthetic rubber intended for use in anti-vibration devices, variations of a large order were encountered. As these variations seemed largely dependent upon temperature, a preliminary detailed examination in the region of 5–40° C. has been made. Using a mechanical vibrator somewhat similar to that employed by Gehman[1] and working at 20–60 c.p.s., measurements of dynamic elastic compression modulus and associated resilience were made by the well-known resonance method. A



detailed description of the apparatus, method and results is to be published later, for the present it may be said that the test pieces were in the form of cylindrical rubber blocks $\frac{7}{8}$ in. in diameter and $\frac{7}{8}$ in. high, bonded at each end to steel screws by the conventional brass-plate method.

The property of an elastic material which is of paramount importance in determining its use as a vibration insulator is the dynamic modulus (in compression and/or shear). In order to compare the temperature variation of a wide range of materials from very soft to very hard, a plot may be made against temperature of relative modulus, that is, modulus at the stated temperature divided by modulus at some standard temperature (20° C. in the present case). Some early results are illustrated by the accompanying curves. The area enclosed by the full lines A and B shows the variation of the modulus-temperature effect in a comprehensive series of 'Neoprene E' (chloroprene polymer) compounds, the dotted lines C and D show the effect for a range of *GR–S* (butadiene-styrene co-polymer) compounds, and finally the broken lines E and F show the effect for a series of natural rubber compounds analogous to those in *GR–S*.

The purpose of this note is to direct attention to the following facts in connexion with rubber-like materials intended for use in anti-vibration devices.

(1) The dynamic modulus has a considerable temperature coefficient.

(2) Quite apart from temperature variations likely to be encountered in service, this fact is of importance in the quoting of dynamic results. The temperature of test should always be stated.

(3) No sign of a temperature effect of this order is evident from static loading tests; in the present work these were carried out using a well-known torsion flexibility measurement.

(4) In view of these facts, the practice of specifying the low-temperature requirements of such products as instrument mountings (anti-vibration) in terms of a static test is likely to lead to wastage of valuable raw materials and labour in the production of articles quite unsuitable for their intended purpose.

Similar results have been reported by previous workers[2], but it is felt that a considerably wider appreciation of such facts would be of general benefit in the present emergency.

Surface Flow of Liquid Helium II and Bose-Einstein Degeneracy

Recently, London[1] has revived the theory of Bose-Einstein condensation and has discussed its application to explain some of the peculiar properties of liquid helium II. A most striking property of liquid helium II is the transport of the liquid over surfaces in the form of mobile films (thickness about 50 mμ) and, as is well known, it is because of the surface transport that the rate of flow of liquid helium II in very narrow channels (less than 10^{-3} cm.) is practically independent of the pressure head.

If v is the volume transferred per second per cm. width of surface, then the values of v for different temperatures, as observed by Daunt and Mendelssohn[2], are given below.

T_0 = λ-point = 2·19° K. $C = \dfrac{v}{1-(T/T_0)^{3/2}}$

$T°$ K.	1	1·5	1 7	1·9	2 1	2 16
$v \times 10^5$ (c.c. per sec.)	7·4	7·5	6·3	4·0	1·2	0
$C \times 10^5$	10·7	17·3	19·9	20 9	19·7	0

It is interesting to observe that for a Bose-Einstein degenerate gas, a flow independent of pressure is realizable, this being due to the flow of the particles constituting the condensed phase (non-energetic particles). The number of particles per unit volume in the condensed phase at temperature $T°$ K. is given by

$$n^* = n[1 - (T/T_0)^{3/2}], \quad . \quad . \quad . \quad (1)$$

where n is the total number of particles per unit volume and T_0 is the λ-point (= 2·19° K.).

If l denotes the thickness of the surface film, then the velocity of the particles in the condensed phase will be $u \sim h/2ml$, m being the mass of the atom. The volume rate of flow per unit width of the film will therefore be given by

$$v \sim \frac{n^*}{n}\frac{ul}{4} = \frac{h}{8m}[1 - (T/T_0)^{3/2}] \quad . \quad . \quad (2)$$

As the accompanying table shows, this relation, so far as the temperature dependence is concerned, agrees reasonably well with observation (the discrepancy is rather serious for the value at 1° K.). Further, the mean observed value of C is about 18, which may be compared with the theoretical value of 12·5 given by equation 2. This agreement appears to be indeed remarkable but, considering the crude nature of the theory, it is to be regarded as more or less accidental.

Effect of Carbon Dioxide and Carbon Dioxide Fixation in Baker's Yeast

DETERMINATIONS of the amount of bound carbon dioxide in yeast cells under known carbon dioxide pressure in the gaseous phase were performed by me originally in order to investigate possible pH changes in the cells under different physiological conditions. This presupposes that carbon dioxide is bound in yeast chiefly as bicarbonate, which, however, according to the experiments described below, is probably not the case. In view of the importance of carbon dioxide in the metabolism of various cells, as pointed out by several workers, and in pursuance of earlier investigations on the physiology of baker's yeast, I have studied the influence of carbon dioxide on yeast metabolism.

The experimental material was fresh, compressed baker's yeast (dry weight c. 26 per cent) suspended in a $M/15$ sodium succinate buffer, pH 5·1 ; temperature 25° C.

The endogenous metabolism of yeast determined manometrically by means of the Warburg two-vessel method[1], as well as its uptake of glucose in the presence and in the absence of ammonium chloride, and, finally, the uptake of pyruvic acid, were found to be markedly higher under constant oxygen pressure and addition of up to 50 per cent carbon dioxide to the gaseous phase than in the controls in a mixture of oxygen and nitrogen. Anaerobically, however, the presence of 25 per cent carbon dioxide did not influence the uptake of glucose. The growth of yeast is markedly inhibited when the gaseous phase contains 50 per cent oxygen and 15–50 per cent carbon dioxide. During the endogenous aerobic metabolism, increased in the presence of carbon dioxide, the 'free' phosphate of the plasma, soluble in trichloroacetic acid, and the amount of orthophosphate passing to the outer solution (cf. ref. 2) were reduced. Anaerobically, carbon dioxide did not affect the amount of 'free' phosphate compared with controls. The experiments show the effect of carbon dioxide on the metabolism of yeast. Moderate concentrations of carbon dioxide in the gaseous phase, however, do not directly injure the cells.

Determinations of bound carbon dioxide in yeast were performed manometrically in trough-shaped Warburg vessels. The main compartment contained 1·50 ml. yeast suspension with 200 mgm. fresh yeast in $M/15$ succinate buffer, the side arms 0·30 ml. of 3·64 M p-toluenesulphonic acid. $\alpha^{20°}_{CO_2}$ of the mixture after tilting was found to be 0·728. Sulphuric, metaphosphoric, orthophosphoric and certain other acids proved to be useless for the fixation of yeast.

Bound carbon dioxide in yeast shaken in a gas mixture without addition of carbon dioxide is very low. For *baker's yeast*, the mean value of the measurements in nitrogen was 25 μl. ; for *starved yeast*, that is, yeast shaken aerobically for about 20 hours, it was c. 15 μl., and for yeast which, directly before the measurements, metabolized glucose aerobically for 2½ hours and which was washed (*fed yeast*), it was 40 μl. Finally, for yeast fed with glucose and ammonium chloride, by which procedure an incipient budding is attained (*budding yeast*), it was found to be 50 μl. carbon dioxide per gm. yeast. In a gaseous phase with 50 per cent oxygen plus 50 per cent nitrogen the respective values were 40, 20, 70 and c. 150 μl. carbon dioxide per gm. yeast. The bound carbon dioxide is markedly greater aerobically than

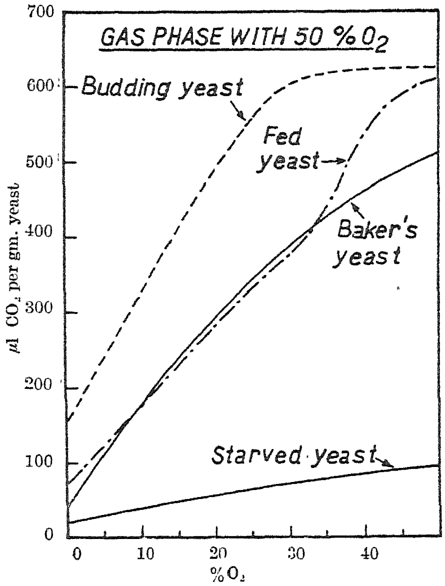

FIG 1.

anaerobically, and it is dependent upon the endogenous metabolism and the thereby conditioned carbon dioxide pressure in the cell.

Fig. 1 shows the bound carbon dioxide of corresponding yeasts in a gaseous phase with an excess of oxygen (50 per cent oxygen) and varying amounts of carbon dioxide. Fig. 2 exhibits bound carbon dioxide at constant carbon dioxide pressure and increasing oxygen pressure. The curves are drawn from the mean values of a great number of determinations. As a consequence of changes in α_{CO_2} during mixing, carbon dioxide is developed in an atmosphere rich in carbon dioxide. Corrections for blank values at different carbon dioxide pressures were made.

The portion of the bound carbon dioxide dependent on the oxygen pressure is bound reversibly and mainly conditioned by the physiological state of the yeast. It is not influenced by illumination with visible light. In experiments on yeasts treated in advance with hydrogen sulphide, cysteine, cyanide, azide or iodoacetate, there was found under aerobic

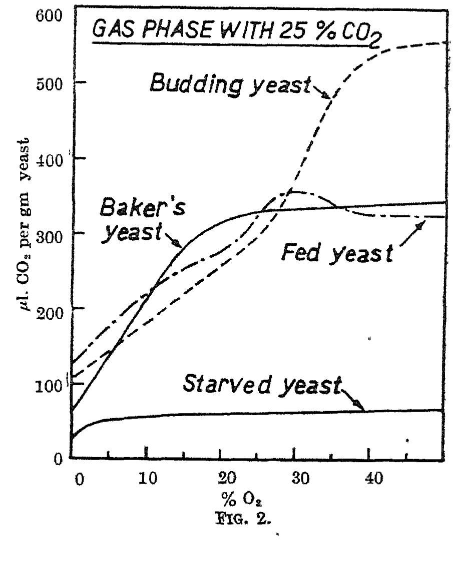

FIG. 2.

conditions a markedly less amount of bound carbon dioxide, similar to that of starved yeast. This indicates that the binding dependent on oxygen pressure is intimately connected with the oxidation-reduction processes in the cell. Brewer's bottom yeast showed a behaviour similar to that of starved yeast.

Calculations of *p*H from the maximum values of bound carbon dioxide, considered as bicarbonate, show that the *p*H in the cells in the presence of carbon dioxide must be increased up to *c.* 0·75 *p*H units above that assumed under anaerobic conditions and the same carbon dioxide pressure (25 per cent carbon dioxide). Such a great change in *p*H has not been verified experimentally. Electrometric titrations (glass electrode) were performed on juice from yeast, fixed rapidly by heating. The determinations indicate that in cells pretreated aerobically with carbon dioxide, this is bound in such a way that a decrease in *p*H is prevented. Under anaerobic conditions, however, this is not the case. Fife and Frampton[3] state that in plant material under the influence of carbon dioxide, ammonia will be liberated from acid amides and the *p*H will thus increase. Where yeast is concerned, I have not been able to confirm this, as the amount of ammonia liberated in the yeast was found to be extremely small, although the juice from yeast cells, pretreated aerobically with carbon dioxide, shows an increase in *p*H measured in absence of carbon dioxide in the atmosphere. Nor is it probable that carbon dioxide would be bound as carbamate (*R*.NH.COOH) at the *p*H in question.

The observations recorded here appear to have some connexion with the investigations performed on different material by Ruben and collaborators with radioactive carbon. Recently, Ruben and Kamen[4] have shown that baker's yeast can assimilate carbon dioxide (at present, the original paper is not accessible in Sweden). It appears probable that the carbon dioxide fixation described above might be interpreted as the first stage in the uptake of carbon dioxide and its further 'assimilation' in the yeast cells, corresponding to the dark reaction described by Ruben's school in connexion with experiments on photosynthesis.

Relation of Scurvy to Histological Changes in the Pancreas

I HAVE shown[1] that the insulin content of the pancreas is markedly diminished in scurvy. In the present investigation attempts have been made to study the histological changes in the pancreas of scorbutic guinea pigs.

Two groups of healthy guinea pigs of weights varying between 163 gm. and 420 gm. were used. One of the groups was placed on a scorbutic diet for 24 days and the other was given normal diet for 15 days[1]. The animals were fasted overnight and killed next morning by a blow on the head. A portion from the tail end of the pancreas was fixed in Zenker-formol solution. Paraffin sections, 7 μ thick, were prepared, and these were stained with Heidenhain's iron hæmatoxylin and Heidenhain's 'azan' stains. In every fourth section from the tail end of each pancreas, stained with iron hæmatoxylin, the number of islets was counted and the size of the individual islets was measured. The results are summarized in Table 1 and the statistical analysis of the individual figures is given in Table 2.

PHOTOMICROGRAPH OF A SECTION OF GUINEA PIG PANCREAS; (*a*) NORMAL; (*b*) SCORBUTIC. × 80.

TABLE 1.

	No. of animals	Number (mean) of the islets in each section	Total (mean) size of the islets in each section (sq. mm.)
Normal guinea pigs	10	7·6	273·52
Scorbutic guinea pigs	10	11·2	1168·25

TABLE 2.

	Size of islets	No. of islets
Difference of the means	894·7	3·6
Standard error of difference	289·16	1·7
t	3·09	2·1
Remarks	Highly significant	Significant

The sections which were stained with 'azan' stain were examined for the different types of cells present in the islets of Langerhans. In the scorbutic guinea pigs, α-cells were found to be increased in number in proportion to the β-cells, and the β-cells were found to be mostly degranulated. There was no degenerative change in the sections studied. Photomicrographs show that the islets are very prominent in the scorbutic condition.

The increase in the size and also the number of islets may be due to Nature's attempt to react against the fall in insulin secretion observed in scurvy. The

absence of any degenerative change seems to be related to the fact that normal recovery takes place when the scorbutic guinea pigs are given supplements of vitamin C.

I wish to express my thanks to Dr. B. B. Sarkar and Mr. P. B. Sen of the Department of Physiology, University of Calcutta, for their kind help.

Growth-Inhibiting Action of Some Pure Substances

THIS preliminary report describes the results obtained with a certain class of growth-inhibitors. Since evidence exists that *H*11 extract contains certain chemical compounds, it was decided to ascertain the inhibitory effects of some pure related substances upon the growth of the Twort carcinoma.

Tumour-bearing mice, averaging 25 gm. weight, were injected intraperitoneally, twice daily, with 0·5 c.c. of the solution to be tested. The surface areas of the tumours were calculated as the products of their diameters, and the group average determined. The inhibitory effect was calculated as the percentage difference between the average increases in size of the treated and the control mice.

Typical results obtained in comparable experiments are summarized in the accompanying table. Mice injected with certain chemicals, for example, anthraquinone, rapidly increased in weight during the course of the experiments, whereas the tumours were inhibited. Tests of substances toxic at higher concentrations, for example, the tannates, showed that, at lower concentrations, tumours were significantly inhibited, the host mice appearing completely unaffected.

Substance tested	Concentration (per cent)	Days of treatment	Percentage inhibition
Sodium tannate	0 25	28	83·3
Calcium tannate	Sat. soln.	8	51·3
1 : 2 : 4-trihydroxy anthraquinone	0·25	14	55 03
1 : 2 : 4 : 5 : 6 : 8-hexahydroxy anthraquinone	0·25	14	81 3
Anthraquinone	0·1	13	46·9
1 : 2-dihydroxy-5 : 8-naphthaquinone	0·25	14	90·6
henanthraquinone	0·1	8	52·1

Badger *et al.*[1] found that some quinone derivatives of carcinogenic hydrocarbons inhibited the growth of the Walker carcinoma 256, and Berenblum and Schoental[2] came to similar conclusions. Other phenolic, aldehyde and quinone derivatives of cyclic hydrocarbons have been tested; the results will be described later.

All these compounds have the property of combining with proteins. Derivatives of vegetable tannins react with proteins because of their polyphenolic constitution, and quinone compounds through their characteristic radicals. The inhibitory effects of these otherwise dissimilar substances are probably directly due to this reaction. A much greater inhibition of tumour-growth than of body-growth was produced. This greater susceptibility to the action of the inhibitors shown by the malignant cells must presumably reside in their intrinsic differences.

Such differences may be accounted for by a provisional hypothesis concerning a modification of cytoplasmic organization in tumour cells. Needham[3] has discussed the organization and differentiation of cells in terms of a cytoskeleton composed of protein fibrils. Wrinch[4] holds a similar view. The hypothesis is that, in the malignant cell, the cytoskeletal components have lost the power of linking up with one another to form a three-dimensional lattice such as may exist in a normal cell.

Fully differentiated cells are unable to divide, but the 'disarticulated' cytoskeleton of a malignant cell, while providing the morphological basis of dedifferentiation, would not hinder division. As the abnormal fibrils would presumably lose the power of responding to the evocator substances which control differentiation, malignant cells would remain undifferentiated and show unregulated growth.

Mottram[5] holds that malignancy results from cytoplasmic modification. The morphological differences between the cytoplasm of malignant and normal cells described by many workers are reviewed by Ludford[6]. The 'disarticulation' of cytoskeletal fibrils would result in such differences. The similarities between malignant cells and embryonic cells might also be explained in terms of the organization of the cytoskeleton.

On the cytoskeletal hypothesis, the various carcinogenic agents would induce malignancy by directly or indirectly modifying the cytoskeletal fibrils so that they no longer link up with one another. The premalignant period would be occupied by the accumulation of abnormal fibrils until their predominance prevents the formation of a normal 'articulated' cytoskeleton.

The mode of action of inhibitors with the property of tanning proteins would be to link up the discrete fibrils of a tumour cell to form a 'pseudo-cytoskeleton'; treated malignant cells would then become stabilized, 'non-malignant' cells, and would be much less able to reproduce themselves, with the result that the whole tumour would tend to regress. This effect of tanning agents on adult, healthy cells with normal cytoskeletons would be relatively insignificant. There may be a similar effect on the mitotic spindle and nucleus.

The cytoskeletal hypothesis furnishes a possible explanation of the site of action of tumour inhibitors which tan proteins and also of various phenomena associated with malignancy.

I am greatly indebted to Mr. J. H. Thompson, director of research of these Laboratories, for constant help and encouragement. My thanks are also due to Mr. C. R. B. Williamson for valuable technical assistance.

Behavioural Changes in Spayed Female Guinea Pigs after Stilbœstrol Administration

In a recent assay of the œstrogenic potency of stilbœstrol, the results of which will be published elsewhere, interesting behavioural changes were observed in our animals.

Altogether 25 spayed female guinea pigs were treated with subcutaneous injections of small priming doses (0·0005–0·0025 mgm.) of stilbœstrol for 6–10 days, and at the disappearance of the vaginal closing membrane this treatment was followed by massive doses (0·5–1·0 mgm.) of stilbœstrol for 2–5 days. Furthermore, five animals, 3–4 hours after the last massive dose of stilbœstrol, received a subcutaneous injection of 0·2 mgm. of proluton.

Within a few days of the commencement of treatment, and while still receiving only small priming doses of stilbœstrol, all our animals became extremely quarrelsome. Cage-mates previously living in peace and amity became pugnacious and bellicose, as shown in frequent fighting during which fairly severe injuries were inflicted, including lacerated wounds in the mid-dorsal region. Finally, it was necessary to house the animals separately during the whole period of the experiment.

There seems little doubt that this unusual and totally unexpected ferocity among the female of the species was a sequel to the administration of stilbœstrol, which induced in our animals a masculine aggression—a component of the male sex-drive.

It appears, however, that the male behaviour such as the mounting activity described by Young and Rundlett[1] is a regular feature of the heat response of the female of many species in which it is integrated into the pattern reaction of a normal *libido*. The androgynous complex has been described in the female guinea pig[2], female rabbit[3], female rat[4,5], the sow[6], the cow[7] and the ewe[8].

Young, Dempsey, Hagquist and Boling[2] relate mounting activity in the female guinea pig to the synergizing action of the œstrin and progesterone of the mature follicles, and this is supported by the findings of Young and Rundlett[1], who produced mounting activity in spayed female guinea pigs by injections of œstradiol benzoate followed by progesterone.

The extension of the male effector responses into the domain of overt sexual behaviour in females seems to indicate that there is some common denominator in the psychic urge motivating the male and the female response, and that the subjective and objective manifestations of the sex drive need not exist as clear-cut sexual differentials but, as in the guinea pig, there may be a certain overlap—the production of a specific hormonal complex.

It is therefore perhaps not altogether surprising that some slight deviation from the normal stimulus such as might be produced by the difference in chemical structure of stilbœstrol and the natural œstrogens should be reflected in the exhibition of masculine aggression. In other respects (copulatory response[9,10], mounting activity, and all the vaginal and uterine preparations) the œstrogenic response of stilbœstrol is normal and complete. This invites the hypothesis that the study of behaviour offers a delicate test of hormonal balance, and is a plea not to neglect altogether the reactions of the higher neurones in any biological assay of the internal secretions of sex.

Counterpart of the Davidson Current

During the period of upwelling in the California Current, it has been said that the California and the Humboldt (or Peru) Currents, on opposite sides of the equator, are "mirror images" of each other[1] (p. 204). Since upwelling is almost a constant process in the Humboldt Current, the similarity disappears when upwelling ceases in the more northern current during late summer, and is not noticeable until upwelling starts again the following March.

Each current has a subsurface counter-current of equatorial subsurface water flowing at approximately 200 metres below the surface. The factor preventing the rise of the subsurface current to the surface in the California Current appears to be upwelling, for, when upwelling ends, the subsurface current rises to the surface and also continues to flow in subsurface levels. Therefore, along the coast of California, from approximately November to January, there is equatorial subsurface water flowing northward from the surface to the shallow sea bottom within the narrow limits of the coastal counter-current.

This inshore, northward-moving, winter current along the California coast was discovered by George Davidson, in charge of the first U.S. Coast and Geodetic Survey of the West Coast, and was named after him. Parenthetically, it is worth remembering that Davidson, who was a scholar as well as a surveyor, wrote the first "U.S. Pacific Coast Pilot". At the outset, it was published by a San Francisco newspaper, because Davidson had difficulty in persuading the Government to print the material since it was undertaken outside his regular duties. He began gathering and writing the first "Pilot" in 1850; the Government publication was in 1858. The book was so helpful to shipping that the demand brought three editions within the next eleven years. In 1880, Davidson was commissioned to revise the "Pilot" again. Evidently he was at last afforded sufficient time to carry out his desires, for, in the nine years that followed, he prepared the monumental contribution, which has not been superseded since its publication in 1889.

Sverdrup[1] (p. 79) states that, during upwelling, the surface waters of the Davidson Current are too disturbed to allow the rise of the subsurface current to the surface. Certain it is, that only when upwelling

ceases or tends to cease does the Davidson Current exist as a surface current.

After reviewing the available data, I have come to the conclusion that a similar situation is maintained within the counter-current under the Humboldt Current.

In the southern winter of 1931, Gunther[2] (pp. 55, 129, 163) found the subsurface, return current at the surface twice—once at Antofagasta (23° 49′ S., 70° 36′ W.), and again at San Juan (15° 30′ S., 75° 12′ W.). Gunther attributed the rise in both instances to the unusually strong upwelling. His description of conditions at Antofagasta is too limited to admit of definite conclusions, for he states that the situation here is unusually changeable.

But at San Juan, the wind was blowing from the south-east—an inshore wind at this point on the coast. Inshore winds tend to terminate upwelling, according to both Schweigger and Gunther. At San Juan, the subsurface current was at the surface for a width of 60 miles, and was flowing against the wind with a strength sufficient to carry the survey ship backward when the wind had a Beaufort Scale force four. A little to the south, and also to the west and to the north, the subsurface current had dropped below the surface.

It seems likely that the inshore wind had caused the upwelling to cease sufficiently at San Juan to allow the subsurface current to rise to the surface, similar to the Davidson Current and for the same reason[3]. The only real difference is that the upwelling in 1931 had ceased only in the vicinity of San Juan; whereas, in winter, upwelling ends throughout the coastal flow of the California Current.

Schweigger[4] has shown that, when upwelling is strong, even large attempted invasions from the north and west of tropical waters into the Humboldt Current area are held back. The data of the International Petroleum Company, Ltd.[6], recorded at Ancon and La Libertad, Ecuador, and compiled during the strong upwelling of 1938 support the same conclusion.

In 1939, the period of weak upwelling, the warm waters succeeded in entering the Humboldt Current area. They did not appear in one compact, surface water mass, but in bands or strips largely separated from the coast and from each other, either by cooler bands, or by successively or alternately warmer strips out toward the open sea. At times, these warm water areas were entirely isolated by surrounding cooler water. At Pisco, the southward moving surface stream was a torrent; yet less than seven miles farther south, the normal cool waters of the Humboldt Current were at the surface[5].

In my opinion, such strips or bands indicate a rising to the surface of subsurface water due to temporary cessation or weakening of upwelling within the Humboldt Current, typical of the Davidson C[illegible]rent. If this apparent tendency proves to be cor[illegible] to Gunther's suggested explanation of strong [illegible]welling, the cessation of upwelling may be added as a possible cause for the rise to the surface of the subsurface current. If oceanographic data concerning low oxygen content in the subsurface waters be demonstrated to be as low as that in the subsurface waters of the east Pacific equatorial regions[1,7], this would offer another probable explanation for the occasional catastrophic death of the rich surface-water life in the Humboldt Current, and also another possible explanation for the appearance in these coastal waters of the mysterious recurrence of hydrogen sulphide, which is locally known as the 'Callao Painter'.

White Plumage of Sea-Birds

The interesting communication from Dr. K. J. W. Craik in Nature of March 4 has inspired me to look up my correspondence with the Government on the subject of war camouflage during the War of 1914–18, and I find, according to the official copies obtained through the Royal Commission on Awards to Inventors, that the letter laying down the principles now popularly known by Thayer's terms 'Counter-shading' and 'Dazzle' was addressed to the then First Lord (Mr. Winston Churchill) on September 24, 1914, and that which laid down the principle that the underside of opaque aircraft should be coloured 'brilliant white' was addressed to the then Secretary of State for War (Mr. D. Lloyd-George) and dated September 28, 1916.

Since these early days, I have had various entertaining encounters with camouflage artists—not to mention high Government officials—who held white to be the most conspicuous, instead of the least conspicuous, colour against a background of sea or sky, except, of course, under special conditions such as at sea when viewed from a high angle, or in the air when viewed against a dark sky or when banking and illuminated on the underside by the sun at a low altitude.

The utility of the white undersurface of aquatic birds and fish in reducing their conspicuousness as viewed from below by their potential prey is, of course, recognized by all field naturalists.

An Early Swanscombe Skull

In all accounts and discussions which I have seen of the important fossil cranial remains found at Swanscombe in June 1935 and March 1936, there is no mention of an earlier discovery of more complete human skeletal remains made in the same locality some time prior to 1913. A few hours before this present note was written, I stumbled across the reference to this earlier Swanscombe skull. This reference is contained in a footnote to an article written by Dr. W. L. H. Duckworth[1].

It would be of great interest to know where these human skeletal remains are now to be found. It is to be hoped that this communication will lead to the location of these remains and to a full report on their history and character.

THE SYCAMORE TREE

By ALEXANDER L. HOWARD

IN company with many other prosperous exotics, the so-called 'sycamore' has lived for many generations in Great Britain under a false name. Sycamore is an attractive name, but as applied to this tree it is both incorrect and misleading: the term *Acer pseudoplatanus* is equally so. The word 'sycamore', spelt by the early botanists 'sycomore', is the name for a fig tree, very well described by Pliny, 69–115 A.D. The botanical term *Acer pseudoplatanus* is inaccurate, as in no respect can the sycamore be considered a spurious or, in modern phraseology, *ersatz* tree. The only excuse which can be put forward is that the leaf resembles the plane in its shade of green, and also in its shape. If this reason be sufficient, then most certainly the botanical name for the wych elm should be *Ulmus pseudo-corylus*, since the resemblance between the leaf of the wych elm and that of the hazel (*Corylus avellana*) is greater. Four authorities of very different dates all bear witness to this long-standing mistake.

Pliny says:

"In Aegypt likewise there be found many trees which grow not elsewhere: and principally the Sycomore, which thereupon is called the Aegyptian Figtree. The tree for leafe, bignesse, and barke, is like unto the Mulberie tree. It beareth fruit not upon the branches, but out of the very body of the stocke. And the same is a passing sweet fig, but without any graines at all within. It doth increase in exceeding great abundance."

John Evelyn (1664):

"The Sycamore or Wild Figtree falsely so-called, is our *Acer Magus* or Broad-leaved *Mas*, one of the Maples."

Students of the New Testament remain under the impression that the tree into which Zaccheus climbed to see Christ pass on his way to Jerusalem was the sycamore as we know it, whereas it was in fact the *Ficus Sycamorus*—the fig mulberry. Even Jacob S. Strutt in his "Sylva Britannica" falls into this error.

William Boutcher, nurseryman, in 1776, writes:

"The greater Maple, in England *falsely* called the Sycamore and in Scotland the Plane tree."

Whether the term 'broad-leaved maple' as in America, the botanical name *Acer macrophyllum*, or *A. Magus*, or any other scientific name should be applied, matters not, but the tree should certainly not be called sycamore or *Acer pseudoplatanus*. In bark, twig, leaf, fruit, and flower, and more particularly in wood, there is no kind of resemblance between the so-called sycamore (English) and the plane. Both trees produce valuable and useful wood, but they are not suitable for similar purposes. Whereas the sycamore is not indigenous to Great Britain, its close relative—the small-leaved or old-English maple—belongs here, as will be seen later. Although the introduction of the sycamore to southern Europe may have occurred at an early date, Pliny does not mention it. The earliest known record is about the fourteenth century, when, according to the Rev. C. A. Johns, Chaucer speaks of it as "a rare exotic".

Elwes quotes:

"Clement Reid hazards the suggestion that it was introduced by the Romans. Ray states, Synopsis 230, published in 1690, that the Sycamore was then planted in cemeteries and about the houses of the nobility, and that it was nowhere wild in England."

All records show that it did not receive a very warm welcome. To quote John Evelyn again:

"the Sycamore is much more in reputation for its shade than it deserves . . . for the honey-dew leaves, which fall early like those of the Ash turn to mucilage and noxious insects and putrify with the first moisture of the season, so as they contaminate and marr our walkes, and are therefore by my consent, to be banished from all curious gardens and avenues."

The Rev. C. A. Johns, and all other early writers, speak of it unkindly, but the sycamore, in spite of this unpopular reception, seems to have become well adapted to its new habitat, and full of life, vigour, and determined perseverance, and has now become established in Great Britain.

In youth it cannot be classed among the beautiful trees of our landscape, but in later age the case is different, and the fully matured sycamore is a noble tree holding its own among its neighbours. While it is certainly surpassed in beauty by its cousin, the small-leaved English maple (*Acer campestre*), it is now an outstanding feature of parks and public gardens, churchyards and stately mansions, where it attains a certain grandeur. The crown in the early spring is clothed with rich green leaves falling in graceful sprays, which later turn to a darker colour, reminiscent of the ebony in tropical regions. As autumn approaches, the small-leaved maple turns to a rich gold, while the sycamore still holds its sombre green, only broken by the appearance of black spot, against which precaution should be taken. While its life may be extended far beyond 150 years, it cannot be said to compare in this respect with our indigenous trees, and the forester should therefore realize that it should be harvested at an earlier age than others—perhaps not later than 80–100 years, after which time the quality of the tree deteriorates. "English Forests and Forest Trees", published in 1853, mentions as the largest known sycamore at that time the tree at Bishopston in Renfrewshire:

"which measured 60 feet in height and 20 feet in girth. This tree is known to have been planted before the Reformation, and is supposed to be not less than 300 years old, yet it has the appearance of being perfectly sound."

But Elwes in 1913 says:

"I think the palm must be awarded to a tree near the Marquess of Ripon's house at Studley Royal, Yorkshire. This tree is about 104 feet high, by 17½ feet in girth. It has a very large burr close to the ground, where it is 29½ feet round, and a clear bole of about 30 feet."

He also mentions another tree at Powerscourt, Co. Wicklow, which "is a fine wide-spreading tree 80 feet high by 14 feet in girth". When I saw this tree in 1936 it was an outstanding example of grace and beauty, and always attracted the attention of many who travelled far to see it.

When felled at its prime, the sycamore tree provides a wood of such exceptional value that for this purpose alone its continued prosperity should be assured. The colour of the wood is creamy white, and the grain close, compact, and capable of an ivory surface—whether straight-grained and plain or beautifully figured with mottle or broken roe and mottle, it is always attractive and comparable to the wood of the same tree which has been imported from Canada and America in considerable quantities. The timber from these sources can be mixed with our own home-grown products, so that they are indistinguishable. When the wood is stained with a

solution it is possible to produce a surface which is so universally admired that it has proved invaluable for decorative purposes such as panelling and interior decoration of houses, and furniture: this production is known as 'hare-wood'. Sycamore has been used for the making of a great number of domestic utensils and furniture in its unstained condition, and for many years has been greatly in demand for rollers for printing linen. In this connexion Elwes mistakenly assumes that the outstanding value of this wood is for these rollers. In actual fact, the great value of sycamore renders it far too costly for this purpose, as the strict selection for quality and waste in conversion, both essential for this work, can only result in a loss.

While its natural colour is not always improved by exposure to light and air, if it is used where continual scouring and cleaning is necessary, it is an admirable medium, and since the eighteenth century it has been much in demand for kitchen tables, counters and the like. The gangway for the admission of Royal personages to King Edward's steam yacht was, by his special command, constructed of sycamore, which by continual scrubbing kept its spotless white appearance.

The small-leaved English maple (*Acer campestre*), improperly called the 'common or field maple', deserves especial attention. Why the undignified term 'common' should have been applied to it is difficult to understand. The dictionary gives as the definition of 'common', "vulgar, mean, usual, and public", but the tree is none of these—there is nothing mean about it, and it is by no means common; in fact, to-day, whatever it may have been in the past, it is uncommon. It is one of the most beautiful trees which ornament the country, principally in parks and surrounding stately mansions. Throughout its life, whether in spring, summer, autumn or winter, it is a graceful feature of the landscape. Unadorned, its branches make a lovely pattern against the winter sky. In spring its tender pale green leaves present a pretty sight. In summer the spread of the foliage is different from all other forest trees; but its full glory is reached in the autumn when the leaves turn to ripe gold.

In the historical place at Cassiobury Park, Watford, the seat of the Earls of Essex, among a unique collection of oaks, chestnuts, beeches, elms and ash trees, there were two early English maples, equal in beauty to any of that noble company, and one of them, probably the best of its kind, was to be found thirty years ago. Its important uses do not seem to have been ever fully recognized. Its suitability for hedgerows has been almost entirely ignored: in such places quickthorn, privet, cypress, yew, ivy, beech, hornbeam and Japanese *Lonicera nitida* are commonly employed, whereas the maple has had to struggle on alone without encouragement. English arboriculturists do not seem to have appreciated either its beauty or its value for timber, which was not the case with those earlier enthusiasts whose writings have come down to posterity. The Rev. C. A. Johns quotes that "Virgil represents one of his kings as seated on a *Maple* throne", and Pliny says "the trunk for beauty and firmness of grain is inferior only to the Citron wood". It is curious to notice that from the time of Evelyn no one seems to have been interested in furthering the claims of this beautiful tree. The timber generally is little known to-day, although it possesses qualities which would have rendered it invaluable in place of wood which has been imported from other countries. In this category may be named American, Canadian, European, Swedish and Norwegian supplies—most of them unknown to the craftsmen of those earlier times, who depended upon their own home-grown timbers for the supply of domestic utensils made of wood. Indeed, the origin of the name 'mazer' for bowls and drinking cups signified the name of the wood from which they were made, the word 'mazer' being a corruption of the old Welsh word 'masarn'—the maple tree. Such bowls and drinking cups were in common and continual use, and were handed down from father to son as heirlooms.

Even ordinary observers will have noticed the habit which many trees exhibit of throwing out all round the trunk, sometimes at the base, sometimes at the crown, and sometimes in between, the growth of tiny branches massed together. This habit is most pronounced in the English or common maple, and is even more abundantly found in similar trees of other countries. Such examples are highly prized and eagerly sought for, and when cut on the rotary machine, round the tree in veneer, the wood yields a product named 'birds-eye' maple. This peculiar growth increases the value threefold and sometimes more.

The ivory-white colour and the quality of the grain of the small-leaved maple enable the craftsman to produce an article which will withstand continual washing and preserve an ornamental surface. While the grain is tough, it is not brittle, and the tool of the sculptor or engraver can work it with satisfactory results in every direction of its growth. As Pliny says, "it is in great request for many exquisite and sumptuous workes".

In the list of trees which the future forester should establish, planting them again and again, the so-called 'sycamore' and the 'common' English small-leaved maple should certainly receive a prominent place. The man who plants these trees will be repaid in full measure, and in a shorter period of time than in the case of most hardwood trees.

BUILDING RESEARCH IN THE UNITED STATES

THE report of the British Building Mission, appointed by the Minister of Works in July 1943, on building methods in the United States, which has now been published by the Ministry of Works (H.M. Stationery Office, 4*d*. net) contains, among much that is of general interest, a good deal of special interest to scientific workers. This is particularly true of the first part of the report, dealing with the design of buildings. The report points out that American designers, knowing that many buildings of no great age are threatened with obsolescence of equipment and general design, show a tendency to assume that, in view of the rapidity of scientific development and social change, future generations of Americans will demand to live and work in buildings evolved by themselves and appropriate to their own times; they appear to believe that many of the buildings of the present should be designed strictly for their immediate purpose, and that a limited life for a building may be an advantage rather than the reverse. American manufacturers are accordingly seeking to produce new materials fulfilling the general requirements of serviceable building but costing less

than traditional materials and not necessarily having the same length of life.

Early specimens of new materials for building construction were inspected by the members of the British Mission, who were informed that when in full production their cost would be substantially less than that of traditional materials. The importance of such developments with reference to the short-term planning of building in Great Britain to deal with the immediate problems of reconstruction in bombed areas needs no emphasis, while the observations on amenities in buildings are fully as relevant to a long-term building plan. The report mentions that the most noteworthy improvements in general amenities, particularly in housing, involved a considerable increase in the consumption of electricity, gas and water; thus the average consumption of water per head of population is more than double the British rate, while a number of plug-in socket outlets for electrical appliances is provided in every room.

A section in this first part of the report is devoted to research and information services. A considerable volume of scientific research is regularly undertaken by various interests including the Federal Government, universities, professional institutions, trade associations, materials manufacturers and organizations financed by private benefactors. The importance of research to American building is fully recognized by all concerned with the welfare of the industry. Large funds are expended, but while the Mission was impressed by the excellence and variety of the equipment in the research establishments visited, and the many channels of contact between research workers, there is no institution in the United States comparable with the Building Research Station in Britain, and greater co-ordination on a national scale is an admitted need. The keenest interest was expressed in many places in the work of this and other research stations of the Department of Scientific and Industrial Research; and British research concerned with the daylighting of schools and with the control of sound transmission in buildings is followed with special attention.

The large number of university-trained scientific workers employed in the American building and manufacturing industries, and the status of these workers, impressed the Mission, which considers that the efficiency of the industry in Britain would greatly benefit by the employment of more research workers and by the adoption of American methods of using scientific personnel. It is also suggested that existing provision for the exchange of scientific papers relating to building and constructional work generally between Government agencies in the United States and in Britain should be broadened, and that regular liaison should be established between the Ministry of Works and development and research organizations concerned with American building, including the National Bureau of Standards. The comparatively few personal contacts between research workers of the two countries appear to have been well worth while, and hopes are entertained of a regular exchange after the War.

In the United States, as in Great Britain, much of the research effort which would normally be directed to the improvement of building and building materials is now being expended in the war effort, and many advances are anticipated in the development of building materials, more particularly in plastics, non-ferrous metals, composite and temporary materials and materials used for thermal insulation. On the other hand, the Mission did not find many new materials in use, nor many new methods of using old materials. The more interesting materials are not yet in full commercial production. In particular, the application of plastics in building is at present inconsiderable. Some use has been made of extruded plastic pipes as an alternative to metal pipes, and the use of plastic sheets having a base of laminated paper or fabric for table tops, sinks, draining boards, etc., is expected to extend very rapidly after the War. The future of plastics in building, however, must depend on the cost of production.

Statistical research is of vital importance to the building industry, and this is well realized in the United States. Among the more outstanding work, the report mentions "The Study of Consumer Purchases", a social survey by the Bureau of Labour Statistics, which includes housing, furnishing and equipment; the Construction Section of the Census of Business, a national survey undertaken by the Department of Commerce in 1939; the regular bulletins on new building issued by the Bureau of Labour Statistics of the Department of Labour; the monthly bulletins of the same Bureau, giving details of labour conditions and trends; the analysis of new house building in selected areas published by the Federal Housing Administration; the annual report of that Administration, analysing building loans insured during the year; and the publications of the F. M. Dodge Corporation covering new building throughout the Eastern States and the Middle West.

Again, the Mission was impressed by the efficiency of American methods of disseminating the knowledge gained by research workers through trade publications and the daily Press, through wireless broadcasts, exhibitions and technical and scientific meetings and conferences. Materials manufacturers realize the importance of supplying architects and engineers with technical information about their products. The general excellence of the presentation of technical data is well exemplified in the information services of the Dodge Corporation of New York, while the small and medium-size instructional exhibition is regarded in the United States as one of the most useful and popular channels for spreading new information. The report suggests that this instrument should be fully used by the Ministry of Works and by the building and manufacturing industries in Great Britain.

One of the most impressive features of this exceptionally interesting report is, in fact, that it illustrates the soundness of many of the arguments advanced in Great Britain for extending the research effort and encouraging a wider utilization of science in industry.

Fuller use should be made of American experience with factory-produced houses, materials for soil stabilization, the moving of entire buildings, repair of damaged buildings by the cement-gun process, materials already in extensive use in the United States such as composite slabs and panels, asphalt floor tiles and pitch for flat roofing, and materials likely to be more widely used after the War, such as plastics and compositions making use of sawdust and other wood waste. In regard to investigations, those on installations and appliances for houses and flats, availability of public utility services, methods of thermal insulation, district heating and hot-water supply, abatement of noise in buildings, standardization of materials and components for quality and

performance and of dimensions of components and equipment and on artificial lighting of buildings, particularly of shops, museums and art galleries, should be pressed forward, while other investigations should be instituted into minimum standards of quality in house design and construction, and standardization generally.

Among the American practices adoption of which is recommended are simplification of design of buildings for greater standardization and for mechanization of constructional work, greater use of factory-produced units and assemblies, increased employment of scientific workers for industrial research in the factory and in the field, encouragement of operatives by spreading information concerning the job and by official recognition of good craftsmanship and greater use of plant machinery and hand-power tools. Finally, the report recommends that legislation be promoted with the object of securing registration of architects and of professional engineers, so that building plans shall be prepared by registered persons only.

SUB-ANTARCTIC AND ANTARCTIC POLYZOA

DR. HASTINGS' extensive monograph on part of the Polyzoa of the Discovery collections includes much careful and critical work*. The six families involved are the Scrupocellariidæ, Epistomiidæ, Farciminariidæ, Bicellariellidæ, Aeteidæ and Scrupariidæ. The last family is, however, included with the Cellularina merely for convenience, and it is not intended to imply that it certainly belongs to that group.

The most important part of the work is undoubtedly the distributional data. Recent hydrological investigations made by the Discovery expedition have been available throughout, and correlation of the distribution of the antarctic and sub-antarctic species with the hydrology gives suggestive results. Thus change of hydrological conditions at the Antarctic Convergence appears to have a decisive influence on the non-abyssal Polyzoa. The presence of species with antarctic affinities in a zone off the Patagonian shelf is probably influenced by antarctic waters, and the distribution of abyssal species is possibly related to warm and cold deep currents.

An interesting fact is the similarity of the polyzoon fauna of Heard Island to that of the other islands in the South Indian Ocean although the hydrological conditions are different. Deacon (1933) has shown that these islands of the South Indian Ocean are hydrologically on the borderland between the Sub-antarctic and the Antarctic Convergence, Heard Island being well to the south and clearly antarctic hydrologically, but there appear to be grounds for regarding the Cellularine polyzoa of the islands, including Heard Island, as sub-antarctic rather than antarctic. It may be pointed out, however, that while Heard Island is connected with Kerguelen Island to the north by a submarine ridge, it is separated from the nearest point on the Antarctic mainland by some eight hundred miles of deep sea, for the so-called Kerguelen-Gaussberg ridge, although it represents a considerable rise in the floor of the great basin south of the Indian Ocean, still shows depths of more than a thousand fathoms over most of its length. The Patagonian region, on the other hand, has a series of stepping-stones with the Antarctic provided by the islands of the south antillean arc. In considering the distribution of a group such as Polyzoa, which are sessile during a large part of their life-history, these facts may help to explain why a correlation with hydrological conditions apparent in one region does not work in the other.

The collection is rich in ancestrulæ (the ancestrula being the first zooecium of the colony formed by the metamorphosis of the larva). These are different from the rest of the colony and important from a systematic point of view. They are only known in a small proportion of the species and much new material is described here. It was thought that these might give evidence of the breeding seasons. Although only tentative, the facts assembled seem to show that the ancestrulæ are more frequently found in the early months of the year, although colonies were collected over a period of from four to seven months.

The report is very well illustrated both by numerous clear text figures and photographic plates.

Issued by the Discovery Committee, Colonial Office, London, on behalf of the Government of the Dependencies of the Falkland Islands. (Cambridge: At the University Press; 1943.) 9*d*. net.

THE GEOLOGY OF RHUM (INNER HEBRIDES)

AT the meeting of the Geological Society on January 19, Dr. E. B. Bailey presented some new facts and a revised interpretation of the igneous and tectonic geology of Rhum. A great dislocation described by Harker in 1903 as a Palæozoic thrust is now claimed as a Tertiary ring-fault with central uplift. Harker was influenced by the curvature of the outcrop of the fault, and by the slump-bedding of the Torridonian which he interpreted as a tectonic structure. He was also misled by a patch of Trias which he mistook for crushed Torridonian; by certain associated banded Lewisian gneisses which he regarded as banded Tertiary igneous rocks; and by a set of Tertiary explosion-breccias which he thought were crush-breccias developed by early Palæozoic thrusting. Bailey considers the outstanding tectonic feature of Rhum to be a block uplift, amounting locally to about 7,000 ft., which took place at the start of the Tertiary vulcanicity and was indirectly responsible for the inter-lava river gravels of the neighbouring island of Canna. The peridotites of Rhum were later than the block uplift; they rose along ring-fissures about a centre well to the west of that surrounded by the great initial ring-fault.

At the same meeting S. I. Tomkeieff described the petrology of the famous ultrabasic and basic plutonic rocks of the Island. The mineral compositions of the rocks and the order of crystallization have been accurately determined and it is shown that the ultrabasic rocks comprise a continuous peridotite-allivalite series which is assumed to have been formed by the crystallization of an already differentiated heterogeneous magma. How this differentiation took place remains the outstanding problem still to be solved. The basic rocks are mostly olivine-eucrites, locally strongly banded. A later boss of granophyre is found to be contaminated along its junction with the eucrite.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Saturday, March 18

INSTITUTE OF PHYSICS (INDUSTRIAL RADIOLOGY GROUP) (in Room 1, Chelsea Polytechnic, Manresa Road, Chelsea, London, S.W.3), at 2.30 p.m.—Open Discussion on Miscellaneous Questions on Industrial Radiology.

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 2.30 p.m.—Mr. W. J. Meredith and Dr. G. J. Neary: "The Production of Isodose Curves and the Calculation of Energy Absorption from Standard Depth Dose Data"; Mr. P. H. Flanders: "A Demonstration of an Optical Contour Finder".

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 2.30 p.m.—Dr. H. M. Finniston and Mr. T. D. Fearnehough: "The Physical and Mechanical Properties of Segregates".

Monday, March 20

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. Franklin Kidd: "Dehydration of Foodstuffs" (Cantor Lectures, 1).

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion of "Industry's Opportunity in Education" (to be opened by Dr. P. Dunsheath).

SOCIETY OF CHEMICAL INDUSTRY (PLASTICS GROUP) (by invitation of the Nottingham Section), (at University College, Nottingham), at 6.45 p.m.—Mr. G. Loasby: "Nylon".

BRITISH ASSOCIATION OF CHEMISTS (TEESIDE SUB-SECTION) (in the Y.M.C.A. Rooms, Stockton), at 7 p.m.—Mr. A. Heron: "Micro-analysis".

Tuesday, March 21

BRITISH ECOLOGICAL SOCIETY (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion on "The Ecology of Closely Related Species" (Speakers: Mr. D. Lack, Mr. C. Elton, Dr. G. E. Blackman, Capt. C. Diver, Mr. G. M. Spooner and Dr. G. C. Varley).

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Mr. P. D. Mehta: "Tribes, and the Caste System of India".

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. J. R. Furlong and Mr. E. L. Hill: "Paper-making Materials of the British Empire".

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at Lincoln's Inn Fields, London, W.C.2), at 4 p.m.—Dr. Geoffrey Bourne: "The Problem of Bone Formation".

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY (at the University, Manchester), at 5 p.m.—Prof. H. W. Florey, F.R.S.: "Some Antibiotics with special reference to Penicillin".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Sir Henry Dale, G.B.E., Pres.R.S.: "Chemical Factors in Nervous Effects", i. "Substances Imitating Nervous Effects—Adrenaline, Nicotine, Muscarine, Acetylcholine".*

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Treatment and Tests for Extreme Climatic Conditions" (to be opened by Mr. P. R. Coursey).

Wednesday, March 22

INSTITUTE OF FUEL (at the Engineers' Club, Albert Square, Manchester), at 2.30 p.m.—Mr. P. D. Kirkman: "The Use of Unfamiliar Fuel in Steam-Raising Plant".

INSTITUTE OF PHYSICS (LONDON AND HOME COUNTIES' BRANCH) (joint meeting with the LONDON AND SOUTH-EASTERN COUNTIES' SECTION OF THE ROYAL INSTITUTE OF CHEMISTRY) (at the Royal Institution, Albemarle Street, London, W.1), at 2.30 p.m.—Dr. L. R. G. Treloar: "Rubber and the Rubber-like State".

Thursday, March 23

TOWN AND COUNTRY PLANNING ASSOCIATION (at the Waldorf Hotel, Aldwych, London, W.C.2), at 12.45 p.m.—Luncheon preceding Annual Meeting; Rt. Hon. Sir Montague Barlow, Bart.: "National Planning and British Industry"; at 2.45 p.m.—Annual Meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at Lincoln's Inn Fields, London, W.C.2), at 4 p.m.—Dr. Geoffrey Bourne: "Vitamin C and the Regeneration of Bone".

Friday, March 24

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Sir Lawrence Bragg, F.R.S.: "Lightning Calculations with Light".*

INSTITUTION OF MECHANICAL ENGINEERS (in conjunction with the MANUFACTURE GROUP) (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. J. F. Kayser: "Surface Finish".

Saturday, March 25

ASSOCIATION FOR SCIENTIFIC PHOTOGRAPHY (at the Caxton Hall, Westminster, London, S.W.1), at 2.30 p.m.—"The Assessment of Lens Performance" (Mr. A. Cox: "General Theory of Lens Performance"; Mr. H. W. Martin: "Lens Types and their Characteristics").

BIOCHEMICAL SOCIETY (at the Courtauld Institute of Biochemistry, Middlesex Hospital, London, W.1), at 2.30 p.m.—Annual General Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PSYCHOLOGIST (full-time) for the Child Guidance Clinic—The Acting Director of Education, Becket Street, Derby (March 22).

SPEECH THERAPIST—The Director of Education, Education Offices, Woodlands Road, Middlesbrough (March 25).

SUPERINTENDENT OF THE METALLURGY DEPARTMENT—The Director, National Physical Laboratory, Teddington, Middx. (March 25)

DEPUTY BOROUGH ENGINEER AND SURVEYOR—The Town Clerk, Finsbury Town Hall, Rosebery Avenue, London, E.C.1 (endorsed 'Deputy Borough Engineer') (March 27)

TEACHER OF ENGINEERING SUBJECTS (in particular Engineering Science) at the Cambridgeshire Technical School—The Education Secretary, Shire Hall, Cambridge (March 27).

LECTURER IN THE MINING DEPARTMENT—The Principal, Technical College, Church Street, Barnsley (March 27).

LECTURER IN PSYCHOLOGY—The Principal, Froebel Institute, at Knebworth House, Knebworth, Herts (March 28).

LECTURER (full-time) IN THE DEPARTMENT OF BUILDING of the Leeds College of Technology—The Director of Education, Education Offices, Leeds 1 (March 28).

DEMONSTRATOR IN CHEMISTRY—The Dean, Guy's Hospital Medical School, St. Thomas's Street, London, S.E.1 (March 31).

METALLURGIST (well-qualified) to take charge of Research and General Laboratories, Heat Treatment, etc., Sheffield Steel Works—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.2048.XA) (March 31).

PROFESSORSHIP OF CHEMICAL TECHNOLOGY—The Vice-Chancellor, University of Madras, Triplicane P.O., Madras, India (March 31, by cable; at the same time advise the Office of the High Commissioner for India, General Department, India House, Aldwych, London, W.C.2).

TECHNICAL DEVELOPMENT OFFICER—The Executive Officer, Bucks. War Agricultural Executive Committee, County Offices, Aylesbury, Bucks. (March 31).

DIETITIAN-IN-CHIEF—The Secretary, University College Hospital, Gower Street, London, W.C.1 (March 31).

DIRECTOR OF THE ELECTRICAL DEPARTMENT (location, Bahamas)—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.773A) (March 31).

BOROUGH ELECTRICAL ENGINEER to the Great Yarmouth Corporation—The Engineer and General Manager, Electric House, Regent Road, Great Yarmouth (March 31).

ASSISTANT CHEMIST for the Shellac Research Bureau at Edinburgh—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.1994A) (March 31).

LECTURER IN THE MECHANICAL AND CIVIL ENGINEERING DEPARTMENT—The Registrar, Technical College, Sunderland (April 3).

SENIOR LECTURER IN MECHANICAL ENGINEERING, and a LECTURER IN BUILDING SUBJECTS—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex (April 3).

GRADUATE TEACHER OF GENERAL SUBJECTS, particularly MATHEMATICS—The Principal, Leicester College of Technology and Commerce, Leicester (April 5).

DIRECTOR OF THE ART GALLERY AND MUSEUMS—The Town Clerk, Council House, Birmingham 1 (endorsed 'Art Gallery Director—Room 1') (April 12).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

DRUMMOND PROFESSORSHIP OF POLITICAL ECONOMY—The Registrar, University Registry, Oxford (May 13).

W. H. COLLINS PROFESSORSHIP OF HUMAN AND COMPARATIVE PATHOLOGY—The Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2 (July 31).

LECTURER IN THE ENGINEERING DEPARTMENT (chief subject ENGINEERING DRAWING and DESIGN up to Higher National Certificate standard) of the Bournemouth Municipal College—The Director of Education, Town Hall, Bournemouth.

EDUCATION OF THE CHEMIST

THOUGH the outlines of the post-war world are still nebulous, it will certainly be an impoverished world, and a world in which Britain will confront immense opportunities but with sadly straitened resources. Times cannot fail to be hard. Even were we to resign ourselves ignobly to the selfish minimum, life would be no pleasant routine of short hours, bread, and circuses. It will be very much more rigorous if, following the deeper aspirations of the national conscience, we accept—and act upon—the belief that Britain has a mission of leadership.

So much is common ground. If we then assume, as we are justified in assuming, that Britain will shoulder whatever tasks are indicated by the finger of duty, we must ask ourselves how best to prepare for what lies ahead. The air resounds with words, but the ideas to be associated with them are often tenuous and elusive. 'Reconstruction' and 'rehabilitation' arouse different images and different reactions in different minds ; even 'planning', to some minds, carries a tang of bureaucratic meddlesomeness which excites a 'never-shall-be-slaves' antagonism. Where we can scarcely be at variance with one another is in postulating that the first necessity at the present time is forethought.

No government, especially amid the exigencies of mortal war, would be capable of taking all the forethought demanded by so critical and so unfathomable a future. It follows that the problem must be partly delegated to, or spontaneously attacked by, individual national bodies capable of dealing usefully with particular aspects of it. A start has already been made in this direction in more than one quarter, and it is very satisfactory to note that, at the initiative of the Royal Institute of Chemistry, serious consideration has been given to the question of the education desirable for young chemists*. It is very satisfactory for the plain reasons that ingenious and economic exploitation of natural wealth will be an indispensable condition of our future existence, and that in this exploitation chemists will be key men. The recruitment of an adequate number of chemists and also their quality and their training are therefore of vital importance. Quality is not wholly controllable. It depends on a complex interplay of biological, sociological, and other factors ; but there is no reason to suppose that coming generations will be any less fertile in chemical ability than those of the past. Training, on the other hand, may be shaped at will, and thus of any proposed scheme of chemical education it is legitimate to ask two questions, namely, whether it is likely to produce a sufficient supply of skilled chemists of various kinds, and whether it affords encouragement for the development of administrative and similar abilities—that is, whether it looks forward to a state of affairs in which the chemist and his fellow men of science will exert in public, industrial and social matters an influence

* The Education and Training of Chemists : Report of the Chemistry Education Advisory Board. Pp. 16. (London: Royal Institute of Chemistry.)

proportionate to their intellectual capacities and to the natural forces they control.

We thus turn with interest to the report of the Chemistry Education Advisory Board set up in 1943 under the auspices of the Association of University Teachers, the Chemical Society, the Royal Institute of Chemistry, the Science Masters' Association, and the Society of Chemical Industry, two nominees of the Association of British Chemical Manufacturers having been later co-opted as members of the Board in order to represent employers. One may note with some surprise that, although two of its fellows were on the Board, the Royal Society was not officially represented; neither was the British Association.

The report deals with its thesis under the following main heads: chemistry in schools, chemistry in the universities, the education and training of industrial chemists and chemical technicians above the minimum school-leaving age, part-time education up to the age of eighteen, the training of chemists in the professional grade, and the supply and training of teachers. It will be observed that while the terms of reference are reasonably wide, they do not embrace, except incidentally, the second of the two questions posed above. Though this may cause disappointment, the omission is understandable, but we hope that the Board—which is probably to remain in being—will repair it as soon as opportunity offers. No feeling of diffidence should hinder full expression of informed opinion upon a matter of such consequence. It is, of course, a sound principle to consolidate each position before assaulting the next, but caution may be carried too far. The present report could well have been the vehicle of a bolder pronouncement upon the part that should be played in the community by the chemist in particular and the scientific man in general.

This criticism must not be taken to imply dissatisfaction with what the report does in fact provide. The contrary is true. The composition of the Board shows it to be widely representative, and the report contains observations and recommendations worthy of the closest possible attention. We may consider some of them here. Since we have referred to the merely incidental treatment in the report of the broader aspect of chemical education, we take first a point in which this aspect is touched upon, so to speak, in reverse. The Board expresses the opinion —in which we fully concur—that it is a matter of great importance "that those, more especially, who will afterwards become leaders in industry and commerce, civil servants and administrators, should become more fully imbued with the spirit of science and should gain both a fuller appreciation of the scientific method and a greater understanding of the power of scientific knowledge and research". The sentiment is unexceptionable; but what we miss is any sufficient suggestion as to how the education of chemists (whom we may regard as typical of scientific workers as a whole) should be modified so that they too might, if they chose, become leaders in industry and commerce, Civil servants and administrators. It is, indeed, a remarkable fact, and we think a deplorable fact, that while many choices of career are open to the man who reads one of the humanities at the university, there is a very much more restricted choice for the science graduate. How far this is due to the structure of society and how far to a remediable defect in university courses may be difficult to determine; but, in spite of such notable exceptions as Sir Stafford Cripps, the rule remains. It is a rule which men of science should exert themselves to eliminate.

Before proceeding to discuss other points of the report, we may make passing reference to the astonishing, and we believe retrograde, opinion of the Board that "for those [post-School Certificate school] pupils who are studying Natural Science as a part of general culture rather than as a part of technical training, practical work in the laboratory need not be required". This may be a majority opinion; there are schoolmasters on the Board, and we find it difficult to conceive that they, who must have witnessed at first hand, and on countless occasions, the all-vivifying effect of laboratory work upon their classes, should have concurred in it. Unless, indeed, we are to look for a clue in a subsequent sentence: "it has to be borne in mind that the time consumed in practical work, if insisted on, may lead, in the case of the pupils under consideration, to the abandonment of instruction in Natural Science altogether". This would provide another example of the Board's apparent diffidence, and one would be tempted to invoke the shade of Danton: "De l'audace, et encore de l'audace, et toujours de l'audace !"

Turning next to the question of university entrance scholarships, we are glad to find that the Board wholeheartedly supports the views expressed by the Norwood Committee regarding the urgent need for a remodelling of these examinations. If the whole basis of the education of the science pupil "is to be broadened, the requirements of the scholarship examination must similarly be broadened", and the examination must give proper credit not only for the special scientific ability but also for the general education of the candidate. In the words of the report, "merely to include subjects of general culture in the school curriculum without giving due weight to them in the scholarship examination, would not prove effective".

In themselves, however, the university scholarship examinations are not solely responsible for the excessive specialization in the post-School Certificate years at school. Part of the blame must be borne by the Higher School Certificate, and the Board recommends that this examination, too, should be suitably modified by the inclusion of non-scientific subjects for the science specialist. This would necessarily mean a somewhat lower standard of attainment in individual science subjects, and therefore ties up neatly with the further opinion of the Board that exemption from attendance at a first-year course at a university is undesirable. Here again we are in full agreement with the Board.

As to the university courses for the intending chemist, the Board recommends that they should be so adjusted as to make possible participation in the general intellectual, social, and recreational life of the university or college. "The student of chemistry should

have time not only to read and think about his specialist studies, but also to mix with men studying other subjects than his own and thereby broaden his general intellectual interests and enlarge his outlook". It is an arresting reflection upon present conditions that such a recommendation should be necessary.

The Board further believes that it is of importance to emphasize that industry requires, and can make use of, for administration, research, laboratory and process operations, etc., not one type alone but many types of chemists, chemical assistants, and chemical technicians, whose education and training may vary greatly and proceed along diverse lines. Opportunity and suitable educational facilities should be provided to enable a worker beginning his career in any one of the lower grades to pass to a higher grade and to attain the highest qualification and professional position to which he may aspire, and for which he shows himself fitted. For these reasons, the Board welcomes the Government's intention to establish compulsory part-time education up to the age of eighteen, and suggests that the special requirements of young chemists should, at the minimum school-leaving age, be reviewed and care taken in assessing their abilities and in giving guidance with regard to their further education and training. This might be done in the larger centres by setting up advisory committees consisting of representatives of the schools, of universities, of technical colleges, of chemists in industry, and of the Royal Institute of Chemistry. Power might also be given to such advisory committees to recommend suitable part-time students for the award of scholarships or bursaries to enable them to continue their education at a university or technical college.

These are sound and practicable suggestions, which clearly ought to be put into operation at the earliest opportunity. The same may be said about the Board's views on the technical education of chemical technicians and chemical works operatives, that is, young employees and skilled or semi-skilled craftsmen who require a knowledge of chemistry and chemical technique but in whom no high standard of academic attainment is needed or expected. Even with such men, however, the Board feels quite properly that the standard of education—general, scientific, and technical—should be raised as much as possible, and that this is one of the main reasons, so far as chemical industry is concerned, why the minimum school-leaving age should be raised and compulsory part-time education introduced.

Two concluding topics treated by the report are the training of chemists in the professional grade, and the supply and training of teachers. On the first, the Board feels that the first three years of a university or higher technical college course should be comparatively free of technology, and that only in the fourth year should technological subjects take first place. On the other hand, during his undergraduate years, the student of chemistry should be encouraged to visit as many industrial works as possible, in order to acquire some insight into the large-scale applications of chemistry and the conversion of laboratory operations into industrial processes. Before the War, vacation courses for undergraduate chemists were arranged by certain manufacturing firms, and the Board hopes that similar facilities, on an increased scale, may be offered by chemical manufacturers after hostilities cease. The Board is also of opinion that it is important to develop much more fully than hitherto the establishment of graduate schools of technological study on lines such as those followed at the Massachusetts Institute of Technology.

Finally, on the supply and training of teachers, the gist of the report is that—particularly in technical colleges—scales of payment are not at present adequate, and that the only way to ensure sufficient teachers of the desired character and calibre is to make the conditions of service sufficiently attractive. That it should be easier to make this recommendation than to implement it is unfortunate, for the provision of the requisite number of competent teachers is patently one of the linchpins of the whole educational vehicle. But experience of the last four or five years has shown that money can always be found when hard necessity calls; and it is for the Chemistry Education Advisory Board and other chemical and scientific bodies to convince the country of the urgent necessity of mobilizing and arming the total strength of Britain's chemical forces.

INDUSTRIAL POLICY AND EMPLOYMENT IN GREAT BRITAIN

THERE is much that is of real interest to scientific workers in the report, "Work: the Future of British Industry", which has recently been prepared by the Sub-Committee on Industry and issued by the Conservative Central Committee on Post-War Problems. In origin and trend, the report is avowedly a party document, but it attempts in the first place—and succeeds in so doing—to show the measure of agreement that already exists on industry and economic policy between the chief political parties in Great Britain. Largely it is a statement of principles, and it clearly owes much to such previous documents as the Unilever paper, "The Problem of Unemployment", the Nuffield College papers on "Employment Policy and Organization of Industry after the War" and "Industry and Education", and sundry others on reconstruction and industrial policy.

The extent to which there is common ground as to the approach to post-war problems and our attitude to them, rather than on the measures by which they are to be solved—for, as will be noted later, the report gives little hint as to a policy—may be illustrated by a few examples. Once again we find emphasized the interdependence of industry and agriculture, the importance of the growth of industrial management as a salaried profession, and of the new educational reforms in widening the sphere of recruitment for such positions as well as in raising the standard of skill. The necessity of developments in technical education is specially stressed; and in welcoming closer collaboration between industry and commerce and the education service, there is a pointed reference to the need to include the universities.

What is said here on the purpose of industry, not merely as producer of the goods required to raise continuously the standard of living for all, to earn the means of paying for the necessaries we must import from abroad, and as a means of livelihood, but also on its being for millions a large part of life itself, implies an attitude which is the real starting point for all human developments in industry and the creation of the right atmosphere for true efficiency. Recognition that the nature of the work, the mental atmosphere, the material environment, the contacts with fellows, with seniors and with subordinates must necessarily enrich or impoverish the lives and outlook of the workers, and through them the life and outlook of the nation as a whole, is the true starting point for developing co-operation whether through joint production committees or in other ways. Once again, we find a welcome for the 'staff college' idea; and the observations on training for management, health services and welfare, hours of work, status and responsibility should be endorsed by all shades of opinion. Moreover, while emphasizing the place of trade unionism and its value as a training for democracy, there is a timely reminder that trade unions were not established to be the preserve of any one political party.

Again, the report faces the future with emphasis on opportunities rather than on difficulties. The prime need is readiness to pioneer and face risks. It is essential to encourage the spirit of initiative, of adventure, of hope, not to go slow and play for safety. In keeping with this, we find that the report not only recognizes the importance of overthrowing all sectional obstacles to human efficiency and restrictive practices, but also, in keeping with other recent reports, urges the need in many branches of industry for a new awakening to the importance of organized research and to the scale on which British industry must further and utilize the advances of science. A major factor in determining the future prosperity of Great Britain will be the full use of our inventiveness and technical skill. More trained scientific workers, a strong development of scientific research in universities and far greater encouragement and scope for scientific men in industry—all these are urged in the report. Once again it is argued that the manner in which experimental and development work is treated for taxation purposes is restrictive and tends to impede application of results of research to the factory, but the need for change in taxation policy comes second to that for an awakening among those who determine financial policy in industry to the part which science has to play in the future of British industry.

On the question of the relations between government and industry the report recognizes the need for building up a practical system of government, but on the broad question of the structure of industry the report is scarcely as open-minded as, for example, Mr. S. Courtauld in some of his recent utterances, and is inclined to prejudge the issue. In accordance with suggestions in Parliamentary debates and in the Nuffield College paper, it regards new measures for training the staffs of Government departments concerned with industry, and especially export problems, as essential, so that they can instinctively appreciate those problems from inside. It calls for dynamic co-operation between industry and Government departments, and looks for a Ministry of Industry and Commerce inspired by a more positive and constructive conception of its duty to help British industry to grow healthily, make good any weaknesses, sell its goods and provide employment. Among its suggestions are a panel of advisers to a Ministry of Industry, chosen from among the best men available in the industrial field, as well as a highly qualified research staff, attached to the Ministry if not to the Cabinet offices, so that, when Government policy is being shaped, expert advice on any relevant aspect can be taken into account.

These suggestions are independent of the general character of industrial enterprise; but there are other comments, for example, on the future of controls and on the location of industry, which represent a large measure of agreement among progressive opinion. The reasons for continuing controls after the War are well formulated, and taken with Sir Stafford Cripps's recent statement and Mr. Bevin's speech to the cotton trade on January 7, should do something to take this question out of the field of faction and place it in its true perspective. In regard to the location of industry, many of the proposals of the Barlow Report are clearly supported. The imperative necessity of ensuring that the national interest is paramount in all decisions in this field, and that it is not obstructed or thwarted by sectional interests, is the crux of the case for the National Industrial Board recommended in that report; although the necessity for central machinery and powers is admitted in veiled terms which do not distinguish between the majority and the minority proposals.

After discussing monopolies, trade associations, etc., the report makes the essential point that is often overlooked in such discussions: technical progress, skilled administration, and good workmanship—these, and not a new political system, can raise the standard of living. A new political system might, of course, contribute to raise the standard in any one of these three directions. The real question is what forms of organization are most conducive to efficient and successful management in any and in every field of industry.

A welcome feature of the report is the support accorded to international co-operation. In the Committee's view, the greatest single cause of the severe unemployment which afflicted practically every industrial country at some time or other between the two wars was the failure of the nations to diagnose unemployment rightly as a world problem, and to collaborate confidently with each other in policies correctly designed to remedy its deep-seated causes. It should be a prime aim of British policy to ease the way to economic collaboration among all the United Nations in accordance with the fifth point of the Atlantic Charter.

The necessity for new developments of international economic machinery is recognized, as well as the expansion and strengthening of existing institu-

tions such as the International Labour Office. Further, a new international currency agency is suggested, whatever differences of view exist about the manner and rules of its operation. General stability of exchange-rates is a prime necessity in laying firm foundations for the recovery and continued growth of world trade, and the provision of massive credits for rehabilitation is given strong support.

The report expresses the hope that the United Nations will also put boldly in hand long-term constructive plans for world prosperity. Stable and reasonable prices for primary producers are necessary, not only for the sake of farmers, but also as an insurance against the shocks which widely fluctuating prices of agricultural products cause to trade and unemployment. As the Hot Springs Conference recommended, a body of broad principles should be reached, through international discussion, regarding the planning and structure of international commodity agreements. The emphasis is laid on regulation, not restriction.

Support is also forthcoming for proposals to raise the economic standards of backward peoples. The awareness of the possibilities in raising standards of living and welfare, undertaken on sound economic and scientific lines, is a welcome feature of the report, which recognizes that the increase in world purchasing power thus created would flow back to become a further safeguard against under-employment in the industrial countries. The report appears to favour entrusting these tasks to international reconstruction and development agencies as visualized by Political and Economic Planning. Here again we find the need for accurate data emphasized, and it is urged that an essential step in stabilizing employment is an international statistical service.

An important section of the report is devoted to export policy in relation to employment. Here, pleading for further government support, the Committee advocates not subsidies but the removal of any handicaps on export business which it is in the power of the government to remove, and the fullest co-operation between industry and government in the examination of acute export problems. The dependence of social security on a policy of employment is recognized, as is the value of public works, though here the report is much more guarded than the Unilever statement. Public works should be treated as a buffer against depression, not as a cure for it; but priority should be given to projects making for efficiency, whether of industry, agriculture or transport, or the quality of our people—a Severn bridge, a road bridge over the Forth, port facilities, and school buildings are indicated.

The report, taken as a whole, is characteristic of progressive thought, independent of party, and the measure of agreement thus indicated as to the direction, if not necessarily of the tempo and methods, of advance should help to eliminate faction and facilitate the initiation of some of the large measures immediately required. Moreover, such agreement should at least facilitate the scientific approach to the problems of reconstruction, and help to secure that, whatever action is taken or policies formulated, they are at least in keeping with the demands of the facts which scientific inquiry has brought to light. The Labour Party's adoption of a memorandum on food prepared by Sir John Orr as its own official policy may well be regarded not merely as a sign of a non-partisan approach to this vitally important problem, but also as an indication of the possibility that party programmes and policies may at least start from common ground in the results of impartial scientific investigation of the technical aspects of the problems concerned.

While in this way the scientific method may help to eliminate the demagogue, it must be remembered that the scientific and technical issues, important as they may be, are, as a rule, only a part of the problem. As to the means of dealing with the social and political aspects, there may well be, and usually are, alternative solutions. Accordingly it is not sufficient, as the Conservative Sub-Committee on Industry has done in this report, to make clear the measure of agreement on objectives. It is necessary for policy also to be formulated, and for the differences between the practical measures proposed by different political parties to be made equally clear. This present report fails to do this, but unless and until it is done (whether for or by the electorate), a democratic system cannot function effectively.

THE BORDERLAND BETWEEN PHYSICS AND MUSIC

The Physics of Music

By Dr. Alexander Wood. Pp. xii+256+14 plates. (London: Methuen and Co., Ltd., 1944.) 21s. net.

DR. WOOD is known to many generations of Cambridge physicists as an excellent teacher of acoustics, and to an even wider circle as a writer of text-books on the same subject. In his latest book he is equally successful in "the very interesting borderland between physics and music" in which so much new knowledge has been gained in recent years. He has written a most useful and valuable book, from which both physicists and musicians can learn a great deal.

The first five chapters expound the general theory of sound, with no very marked emphasis on music, and lead up to a good chapter on the ear and the mechanism of hearing. The next three chapters deal fairly exhaustively with the production of sound by musical instruments—strings, organ pipes, the human voice and orchestral instruments, both wind and percussion. Then come four varied chapters on dissonance and consonance, on scales and temperament, on the mechanical and electrical reproduction of sound, and on the acoustics of halls and concert rooms. This last is a most valuable chapter—or would be if everyone would read it who ought to. For, although the situation has greatly improved of late, many of our auditoria form standing monuments to a want of co-operation between scientific men, musicians and architects. Here Dr. Wood tells us what can be done and what ought to be done. "Probably," he says, "there is no direction in which co-operation between the musician and the scientist is likely to be more fruitful than that of designing auditoria for music," and the same might have been said of rooms for speaking.

The general reader will find much to interest him as he browses through the pages. He may, for example, be surprised to learn how very sensitive a physical instrument the ear is. A softly played violin gives out only 0·0000038 watts of energy, and yet will fill a good-sized room with audible sound. At a pitch of about 3,500 cycles, the ear can hear waves of sound with an amplitude of motion of less than a hundredth part of the radius of the atom. There is, of course, an obverse to this picture, and we read that all the shouting and cheering at a cup-tie match generates just about enough energy to warm a cup of tea.

The flexibility of the ear is equally striking. A full orchestra emits about 20 million times as much energy as the solo violin just mentioned, yet the ear can register both sounds in comfort and with judgment and discrimination. In technical language, it can deal with sounds of from 0 to 130 phons, where each phon represents an energy-increase of about 26 per cent. Dr. Wood brings home to us the vastness of this range by remarking that one twin crying may give a loudness of 60 phons, while the addition of his brother twin will only raise this to 63 phons. Yet the ear works efficiently up to a loudness of 130 phons—10 million babies crying in unison. After this it is not surprising that we come to the "threshold of pain".

In so far as it is concerned with music, the book necessarily treats sound in a somewhat subjective way. Sometimes we may perhaps wonder if this tendency does not go too far, both in the book and outside it. For example, we read on p. 44 that "pitch is not simply dependent on frequency, but depends also on loudness". By way of confirmation, we are told of experiments by Stevens and Snow in which pitch was found to vary with loudness to a maximum extent of 2½ full tones—a fourth. "The pitch of high tones rises with increased loudness, while the pitch of low tones falls with increased loudness." All this seems to make nonsense until we discover that Dr. Wood defines pitch as a "subjective quality of a sound"; it is "the characteristic of a sound in virtue of which we describe it as high or low". When the *A* of a violin is tuned to the *A* of a piano, a musician will say that the two tones are of the same pitch but of different timbre, meaning that the fundamental and its various harmonics enter into the two sounds in different proportions. But a non-musical listener may describe the violin note as being of higher pitch, because he hears more of the higher harmonics than in the piano note (actually Seashore finds that when the open G is sounded on the violin, the amazingly small fraction of 0·1 per cent of the energy resides in the fundamental, as compared with perhaps 20 per cent for the piano). Now Dr. Wood apparently bases his definition of pitch on this kind of non-musical judgment. The results might well have been disastrous, but happily are not. For within five pages the author has forgotten his own definition of pitch, and is telling us of the new international standard of pitch, "440 cycles per second for the note *A* in the treble clef", with no mention of the loudness with which the note *A* is to be sounded. The matter is not wholly unimportant, in view of recent attempts to use the experiments just mentioned as proof that musical theory cannot be based on scientific principles. If pitch varied with loudness in the way claimed, every chord of music, as it died away into silence, would resolve itself into a succession of ghastly discords, in direct contradiction to the experience of every musician who has ever listened to music.

On this particular question, true music and true science are probably in full agreement; but there are a number of other questions on which they are inclined to give different verdicts. In particular, there is the question of whether distinctive emotional characteristics are associated with the various keys in which music can be written: Is the emotional quality of a piece changed when it is transposed from *C* to *D*—or even from *C*♯ to *D*♭? Many musicians say yes; they can recognize an emotional change, even when the music is performed in equal temperament (in which case the various keys differ in nothing physical except pitch, and *C*♯ and *D*♭ do not even differ in this). Most scientific men think this is a pure illusion, or at best a carry-over of associations from a time when equal temperament was unknown. Dr. Wood discusses all such problems very judicially and fairly. If any criticism is to be made, it is that he stands too modestly aloof; his summing-up gives but little guidance to the jury.

The book gives an adequate account of the large amount of acoustical research carried out in recent years, especially in the United States; in general it is well-written and readable, interesting, authoritative and accurate. Thus it can be warmly recommended, and especially to those musicians who wish to know more of the science in which their art has its roots.

J. H. JEANS.

THE NEW ORDER IN INORGANIC CHEMISTRY

Inorganic Chemistry

By Fritz Ephraim. English edition by Dr. P. C. L. Thorne and Dr. E. R. Roberts. Fourth edition, revised. Pp. xii+922. (London and Edinburgh: Gurney and Jackson, Ltd., 1943.) 28s. net.

THE standard text-books in advanced inorganic chemistry at the service of past generations presented the reader with a gigantic jumble of disconnected data. One great unifying principle—the periodic classification of the elements—was indeed recognized; but it was admittedly riddled with exceptions. Small wonder that the majority of students, on reaching the research stage, preferred the severely systematic field of organic chemistry; order is always more attractive than chaos.

To-day the state of affairs is different. Our detailed knowledge of atomic structure, founded on the work of Rutherford, Moseley and Bohr, and our disentanglement of the vexed topic of valency into distinct types, dependent upon the extent to which electrons are transferred or shared between combining atoms, render it possible to develop inorganic chemistry as a coherent whole. The volume under review affords an outstanding, though not a unique, example of the success that can be achieved in this direction. It is true that it is not suitable for the beginner—a very solid basis of elementary facts must still be accumulated before any general theories can be built upon them—but it will undoubtedly appeal to the more advanced student, provided he is not deterred by the first few chapters. These are, perhaps necessarily, very heavy going, but the tension eases as the book proceeds, and the last chapters in particular are packed with material that cannot fail to fascinate and instruct even the expert.

The success of the volume, first issued in English in 1926, is proved by the present attainment of its fourth edition. Each revision has introduced marked improvements. The original text, although good in general, contained a number of almost unbelievable 'howlers'; these have now been carefully eliminated and only a few minor defects remain. For example, the simultaneous presentation of the old idea that a positive charge on an ion is something tangible that can be handed around, and of the newer conception that a positive ion is produced by the loss of an electron (pp. 151, 155, 163), is bound to cause confusion. The fact that the reaction $2Cl_2 + 2H_2O \rightleftharpoons 4HCl + O_2$ is effectively reversible, while the reaction $Cl + HBr = HCl + Br$ (presumably Cl_2 and Br_2 are intended here) is not, cannot be explainable by the statement (p. 218) that the electro-affinities of the elements competing for the hydrogen are more similar in the former case, since exactly the opposite is true (see the table on p. 15[illegible]). A similar inconsistency is the inclusion of nitrous acid in the list of substances illustrating Luther's rule (p. 376), according to which nitrous acid must be a more powerful oxidizing agent than nitric acid, followed later (p. 69[illegible]) by the remark "nitrous acid is a somewhat weaker oxidant than nitric acid". The "change in volume" factor cited as the primary influence in determining the heats of solution of gases, liquids and solids (p. 401) is generally insignificant compared with the "change in state" factor, which is not even mentioned.

Direct references to original investigations are numerous, and useful instructions to the student on how to look up the literature before commencing a research are furnished in a special appendix. Unfortunately, the editors have not always followed their own precepts, and several inaccuracies in the text-matter are directly attributable to the antiquity of the accompanying references. Instances are the polyammines of the hydrogen halides (p. 6[illegible]6) and the acid sulphates of the alkali metals (pp. 581–2).

These, however, are merely subsidiary blemishes in a volume which, on the whole, reaches a very high standard and merits the most cordial recommendation.

JAMES KENDALL.

THE END OF THE NATIONAL STATE

The Crisis of the National State

By Dr. W. Friedmann. Pp. ix+198. (London: Macmillan and Co., Ltd., 1943.) 12*s*. 6*d*. net.

DR. FRIEDMANN has developed in this book a striking theme that demands attention. This is that the National State, by a species of historical dialectic, has reached the end of its development and now passes over into neo-imperialist forms. There is no book on political theory that I have seen during the past year to compare with it in brilliancy or one that I would more readily put into the hands of statesmen and politicians.

It is relevant to Lord Halifax's recent proposals that Dr. Friedmann regards the British Empire as not one of the world's *Grossraum-ordnungen*. "It lacks the essential features of *Grossraum*: unity of space and communications, and consequently economic self-sufficiency in the face of modern war. The British Empire is, indeed, the expression of a past phase of Empire". Like the Habsburgs, the British monarchy and Government have concerned themselves with building up higgledy-piggledy a heterogeneous collection of estates, without cultural or any other unity, all over the map. To put Dr. Friedmann's contention in a more brusque form, the British Commonwealth, in abstraction from the West, including the United States, has no future. A brief inspection of geography and population factors should show us this truth, but, for obvious reasons of prestige, politicians will not attend to these considerations until the time comes when it is too late to unify the West, too early to unify the world, and world direction must necessarily pass into more vigorous Eastern hands. Having won the War we shall have effectively ended in the humiliating position of France in 1918, which explains her obeisance to the inevitable and her fall in 1940.

Dr. Friedmann's major theme, however, is based on a study of German nationalism. This, reaching a paroxysmic intensity in Nazi racial theory, then undergoes transformation (comparable to Roman imperial transformation from the close corporation of *cives Romani*, claiming patrician descent from Romulus) into a new imperial form, where Hitler is frank to admit that there is little opportunity for German nationalism as distinct from membership of an international ruling order of administrators and secret police. The logic of nationalism, as group appetite for power, is that it moves from being power for my nation into being my nation's power supranational over other nations, that is, national imperialism, and then into being power for all bureaucrats, of any nationality, who can functionally contribute to maintain the supra-national imperial power.

The weakness of most contemporary theorists is either that they under-estimate the factor of power, and believe in some kind of liberal pre-established harmony where every country keeps its own army solely to distribute U.N.R.A.'s food supply, or that they seriously believe that any accumulation of power can solve the essentially mental problems of human psychology, ambition and discontent, to-day idealized as 'dynamism'. We suffer from an absence of police which we have never had since Rome fell; and from a breakdown of humanistic education in civilized corporate living which is quite recent—and is expressed by the nihilism of Sorel. Dr. Friedmann fully appreciates the first point, but (unlike Dr. Mannheim) does not dwell on the second.

Dr. Friedmann concludes by favouring regional federal associations or multi-national associations within the framework of a world institution of the United Nations. As touching the orthodox theories of technico-economic organization—the form of 'functionalism' criticized by the present writer elsewhere (*Contemporary Review*, Sept. 1943)—Dr. Friedmann points out that, far from economic necessity compelling internationalism, to-day new developments permit, to some countries (for example, the United States and the U.S.S.R.), regional autarky as never before. Further, "the various political philosophies which dominate international politics in our time are at one in subordinating economic and technical developments to political will. It depends more and more on the latter whether economic conditions will be developed on a national or international scale". The Roosevelt-Eden school of economic-technical collaboration, vestigial from the epoch of economic man, shirks the major issue of a common political will, because it wishes to do so, and is already out of date in the politics of power.

GEORGE CATLIN.

BRAIN RHYTHMS*

By PROF. E. D. ADRIAN, O.M., F.R.S.
University of Cambridge

IN 1929 Prof. Hans Berger, of the Psychiatric Institute at Jena, published the results of some work on which he had been engaged for many years. He had set out to record the electric currents developed in the human brain, and had shown that if metal electrodes were fixed to the scalp, it was possible to detect a regular oscillation of electrical potential which was not due to muscles or skin glands or any other source outside the skull, and could only have come from the nerve cells of the cerebral cortex. The oscillation had a frequency of 9–10 a second. It only appeared when the subject was at rest with attention relaxed and eyes closed; but it obviously represented some kind of continuous activity in the brain covering a fairly large area. What he discovered was then quite unexpected. It has made us revise many of our ideas about the brain and has brought us a little nearer to understanding what goes on in it.

The oscillation, Berger's α rhythm, represents a very small change of potential, about 50 microvolts, and a very small ebb and flow of current in the cerebral cortex. There is nothing unexpected in the fact that brain cells develop small currents when they are active, for all active cells do so. The unexpected thing is the regularity of the rhythm. It is true that if it were not so regular, it might never have been detected, but the regularity means that large numbers of brain cells must be working in unison at the same rate. We should have expected something much more complex and variable—activity varying from moment to moment and from place to place—and not the uniform pulsation shown in a typical record of the electroencephalogram.

We should have expected this because the brain is a great sheet of nerve cells and interlacing nerve fibres, and its working must depend on the spatial distribution of activity in it. This is determined by the particular pathways which must be taken by the incoming and outgoing messages, for the messages are all in the same form wherever they come from, and it is because they arrive in different regions that we interpret one as sight and another as sound. We know, for example, that if one looks at a bright cross, the initial event in the brain will be the activation of a more or less cross-shaped area at the back of the occipital lobe, and that if one hears a sound a pattern will be reproduced in the temporal lobe corresponding to the areas of vibration in the cochlea. All the external events of which we are aware are recorded as spatial and temporal patterns of excitation in the sense organs. These patterns are reproduced in the brain with a good deal of editing, omission of details and heightening of contrasts, and it is from them that we reconstruct our external world.

Now the α rhythm of the electroencephalogram comes from large areas in the occipital region and to some extent from the frontal area as well. At first sight this seems to leave little room for all these diverse patterns of electrical activity. But actually the regions where the potential change is at a maximum are not those where the messages from the sense organs are received in the brain, but are the neighbouring 'silent' or 'association' areas. Also, to make the rhythm appear, the eyes must be closed and the attention relaxed, so that the brain is relatively inactive, at least so far as vision is concerned. Thus the regular wave sequence is derived from certain parts of the cerebral cortex when these have little to do. The cells there are not concerned with the incoming signals and so will be free to beat in unison, and if fairly large areas are so beating our records from the head will show the α waves and will not show the small local irregularities which are probably going on all the time so long as we are conscious.

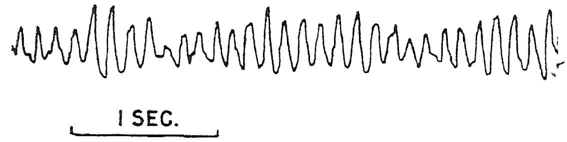

FIG. 1. NORMAL ELECTROENCEPHALOGRAM SHOWING THE α RHYTHM. THE MAXIMUM POTENTIAL CHANGE IS 45 MICROVOLTS.

The cells of the cortex might beat like this when they are left alone because this is how they are made; because like heart muscle or ciliated cells they cannot remain alive and inactive; or the beat might be imposed on them by rhythmically active cells in some other part of the brain which can act as pacemaker to the association areas. Wherever the pacemaking region may be, the important fact is that the rhythm is much the same from one person to another. For clinical purposes, therefore, an electroencephalographic recording can be used as an index to show whether the brain is working normally or not, and for this reason it has become an important technique of clinical neurology. Apart, however, from the value of these records as a means of diagnosis, there is the problem of their significance in relation to the normal mechanism of the brain and of the mind. Do they tell us anything about the neural accompaniment of perception and thought?

The statement that one can record the electrical activity of the brain through the skull raises the hope that one should be able to detect all sorts of brain events connected with consciousness. The hope begins to fade when it is realized that the main feature of our records is a rhythm from nerve cells which are relatively inactive. But there is something of interest to be learnt from them. It is true that we cannot yet record the detailed activities of different parts, but only the gross changes when a whole area goes into action; yet these do give us some novel information about the physical accompaniments of thought and in particular about the process of attention.

To begin with, it seemed that the α rhythm was much less interesting. It might have been merely a spontaneous beat of the nerve cells in parts of the cortex, particularly those concerned with vision—a beat developing whenever the cells were not stimulated by messages from the eyes. Opening the eyes would break up such a rhythm in the receiving area, because the visual pattern there would mean that different groups of nerve cells would be discharging at different frequencies. Something of this kind can certainly happen in the regions where a message enters the cerebral cortex, for in records from the exposed brain (in anæsthetized animals) the arrival of a message in the receiving area produces small, rapid waves in place of the slower and larger α

* Friday Evening Discourse at the Royal Institution delivered on February 4.

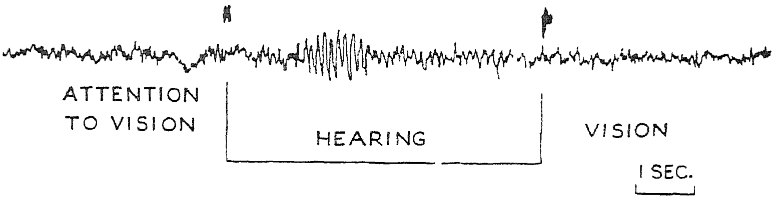

Fig. 2. The α rhythm appears when the attention is transferred from vision to hearing. The visual field has been made unattractive by + 10 *D* spectacles during the middle section of the record the attention is concentrated on the tick of a watch.

rhythm. But the α waves are not confined to the receiving areas of the brain, and it can be shown that in fact the presence or absence of messages from the eyes is not the essential condition for the disappearance or return of the α rhythm.

As far as vision is concerned, what really determines the presence or absence of these waves is not whether visual messages are or are not coming into the brain, but whether we are or are not attending to them—whether we are looking at anything. Man is a visually controlled animal, and if our eyes are open there is usually something in the visual field which catches our attention or some part of it. This is not true for all mammals; the rat and the cat seem to rely more on other senses and can be quite inattentive to sights. But with us the only sure method of shutting out sights from the mind is to close the eyes. Normally, therefore, opening the eyes means that we start looking, or that we become attentive to the visual field. The α waves then disappear, and they return when we close our eyes and cease looking. But shutting the eyes does not cut out all light from the retina, and the α rhythm appears in the brain however much or little light may be falling on the closed lids. Even in a pitch-black room, if we open our eyes and start trying to see something, the rhythm goes, although opening the eyes cannot have altered the illumination of the retina. Sooner or later, when we have given up the attempt to see, the waves will return although the eyes are still open.

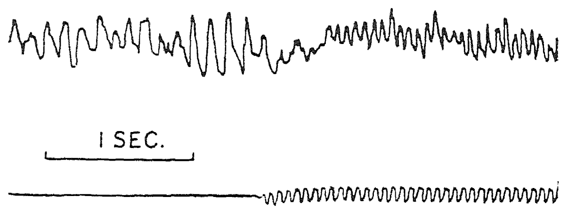
What matters, therefore, is not the excitation of the retina but the turning of attention to the visual field or away from it. This can be shown even more clearly in another way. In daylight and with the eyes open, the attention can rarely be abstracted completely from vision except for short periods; something keeps on 'catching the eye' and coming into the mind, even though we have most of our attention fixed on other things, a sound or a smell, for example. The reason why the visual field cannot be completely ignored is that the picture of it in our brain has patterns and sequences which arouse interest by recalling memories or starting some new train of activity. But if we can make the visual field convey less meaning, it will cease to be so attractive and our attention can leave it more easily. A simple way of securing this is to wear spectacles which will throw everything out of focus. When this is done, although the eyes remain open, the α rhythm will appear much more readily than when the visual field is in its proper focus. With the field blurred, we have only to listen intently to a sound and the α waves will begin, to cease again if we transfer our attention back to vision. Here, too, there has been no change in the illumination of the retina but only the shift of attention. It may be noted that it is not only the intellectual interest of the field which holds our attention. Any movement in it or any sudden change of illumination will do so; and there is a great variation in the ability of different persons to detach the attention from vision, and in the same person at different times.

All this shows that the α rhythm is an activity which appears in the cerebral cortex when the attention is not directed to vision, and disappears when it is. The mental act of looking somehow prevents the α waves from developing in certain parts of the brain, parts which are likely to be concerned in analysing the visual pattern. The α rhythm is therefore a rhythm of inattention, a positive activity which fills those parts of the cortex which are for the moment unemployed. It is not the basic rhythm of unstimulated nerve cells, and there must be some kind of competition between the message from the eyes and from the source of the α rhythm to decide which shall control the cortical areas.

To examine this competition in more detail, we must have some way of recording the sensory activity of the brain as well as the α activity. All the messages which reach the cortex will produce their own electrical accompaniment, and this can be recorded well enough if electrodes can be placed on the surface of the brain. But if we can get no nearer than the scalp, the potential changes generated in any group of nerve cells will usually be obscured by those of other groups near by, and the record will then show us nothing. Fortunately this difficulty can be overcome, in part at least, by making all the cells work in unison. This can be done, as far as vision is concerned, by making the field more or less uniform and lighting it with a flickering light. The nerve cells are then forced to work in unison at the frequency of the flicker, and we can record their electrical activity through the skull up to frequencies of about 30 a second. This gives us a method of tracing the visual messages in the brain, for by means of the flicker rhythm they can be made easy to recognize.

Provided that the flickering area is in the centre of the visual field, it need not subtend more than a few degrees at the eye to give a potential oscillation at the same frequency in the occipital region. The waves are more or less where one would expect them to be, in the right occipital region if the left half of the field flickers, and vice versa. But the flicker waves are not confined to the visual receiving area: they are found also in the neighbouring areas, those from which the α waves come when the eyes are closed. The flicker area is not so large as the α area, but on occasion as much as a quarter of the brain surface seems to pulsate with the flicker rhythm. The retinal messages must then have spread widely and impressed their rhythm on some of the association areas of the cortex.

Now if the eyes are open, the flicker will keep the visual attention engaged and the α rhythm at bay. But if the eyes are closed and the flickering light is thrown on the closed lids, the subject will be conscious of the flicker but the conditions will favour the α rhythm, since closure of the eyes is usually coupled with the withdrawal of attention from vision. In these conditions the two rhythms can be seen to compete for the cortex, and sometimes to co-operate if their frequencies allow of it. The flicker-rate will sometimes appear in patches with the α-rate in between, and if a rapid flicker is turned on suddenly



FLICKER

FIG 3. ELECTROENCEPHALOGRAM FROM THE OCCIPITAL REGION, SHOWING THE CHANGE FROM THE α RHYTHM TO THE FLICKER RHYTHM WHEN THE EYES ARE OPENED AND THE SUBJECT LOOKS AT A SCREEN LIT BY A FLICKERING LIGHT. THE RATE OF FLICKER (17 A SECOND) IS SHOWN BY THE PHOTO-ELECTRIC CELL RECORD BELOW.

the area of the brain giving the flicker rhythm may be large at first and may then shrink rapidly, giving place to the α waves but persisting longer in regions nearer the visual area. If the flicker is made equal to or twice the α-rate, we may find the two summing up to give very large regular waves. Such a combined rhythm usually takes some time to build up as the two sets of waves have to be synchronized, but there is evidently an interaction between them and a tendency to remain synchronized as long as their frequencies are not too far apart. These wave effects vary from one subject to another and there are variations according to mood, time of day, etc.; in general, the sleepier the subject the more the α rhythm will predominate, and the brighter the flicker the more persistent will be the flicker rhythm.

The interaction and interference of these rhythms shows how the cortex, or certain parts of it, may be put at the disposal of our attention. If we decide to look, or if it is decided for us by something 'catching our eye', a change occurs which prevents the α rhythm from occupying the regions surrounding the visual receiving area. If we can turn our whole attention to a watch ticking, the α rhythm comes back. What brings this change about ?

The evidence is still rather scanty. It is likely that the whole of the cerebral cortex is concerned, in that it is the balance of activity in every part which determines where the attention will turn and how long it will be held in one field; but the executive act, the direction of the attention to the particular field, is probably carried out by a relatively small central region in the neighbourhood of the thalamus and near the main incoming pathways. It is from there that the α rhythm seems to be controlled, and it is at least probable that it is the sudden disturbance of this region which causes the loss of consciousness after a blow on the head. This central directing region must act on information received from the cortex, for it will be all the memories and associations stirred up by a stimulus which will determine its interest, and these are presumably not aroused until the message has reached the cortex. But the central region must balance up the conflicting claims of different stimuli and must then decide which should have the main share of the attention, its function resembling that of a central university committee which has to decide which branch of learning should be supported by the next benefaction.

The visual stimuli always get the lion's share. If they are at all interesting, the central region will suppress the α rhythm over the occipital area, so that the visual pattern has a considerable part of the cortex set free for its analysis. When the visual pattern ceases to be interesting and the attention is directed to sounds or other sensory messages, the occipital lobe is not turned over to those but is filled again with the α rhythm. This is shown very clearly in records in which the visual waves are made recognizable by the use of a flickering light, and if the flicker happens to be at twice the α rate a partial diversion of attention will be enough to give the large compound waves at the α frequency.

Apparently the occipital part of the brain is used to analyse sights, and sights only. What parts deal with the patterns aroused by sound and touch we cannot yet say. The areas seem too small to be easily detected, and must certainly be much smaller than the areas which deal with vision. On the other hand, a concentrated mental effort may sometimes abolish the α rhythm although the eyes remain shut. Presumably in this case the whole of the α area may be turned over to non-visual activities.

There are still many gaps in the evidence, but there is much to support the view here put forward, namely, that there is a deep-seated part of the brain which contains the mechanism by which attention is directed one way or the other, and that the α rhythm is under the control of this region, if it is not directly produced by it. If this is so, it is not difficult to understand that abnormalities in the α rhythm are often associated with abnormal kinds of behaviour. The most valuable application of the electroencephalogram in medicine is in the localizing of diseased regions and tumours of the brain by the change in the character of the waves. Another is its use in detecting the sudden explosive discharges of the nerve cells which occur in the brains of epileptics. But quite apart from such obvious disorder of the brain cells, the electroencephalogram may show an α rhythm which is definitely abnormal, irregular, faster or slower than usual or with odd-shaped waves, and in a significant proportion of the subjects who give such records there are abnormalities in the mental or emotional sphere which may be a serious handicap. There are, of course, many factors besides the constitution of the brain which determine whether we react like our fellows or not, but the brain is a not unimportant factor and the electroencephalogram seems to offer a means of assessing some of its deviations from the normal. It remains to be seen whether its use for this purpose will have much practical value: at present the most that can be said is that if we had to appoint someone to a responsible post and had an unlimited field of candidates, it would be safer to exclude the five per cent whose electroencephalogram showed the most unusual features.

That is a very long way from saying that the electroencephalogram can tell us how the subject will think and act. In fact the information which it gives relates to a very limited field. But the limitation arises mainly from the fact that we can only record the gross effects and not the detailed patterns in the brain. With present methods the skull and the scalp are too much in the way, and we need some new physical method to read through them. We need the "patent double million magnifying gas microscopes of hextra power" with which Sam Weller thought he might be able to see through "a flight o' stairs and a deal door". In these days we may look with some confidence to the physicists to produce such an instrument, for it is just the sort of thing they can do; but until it is available we have to confess, with Sam Weller, that "our wision's limited".

A SOCIAL MEDICINE BASED ON SOCIAL STATISTICS

By Prof. P. SARGANT FLORENCE
University of Birmingham

1. Experience in Industrial Fatigue

THIRTY years ago I was appointed investigator to a committee set up by the British Association, meeting at Birmingham, to study "Fatigue from the Economic Standpoint". I took 'economic' as a clue pointing me *toward* the external behaviour of men at work and pointing *away* from studies of the physiology of fatigue internal to a man. The data at my disposal were thus confined to the external conditions likely to influence a man's work and the external tests of a man's efficiency at work. The findings which I first reported[1] about the effect of such conditions as long hours or different types of work upon such tests of efficiency as output and accidents gradually developed into a scheme of study, published in 1924[2], which I have found a useful framework for co-ordinating the results of subsequent inquiries. The scheme is here presented in bare outline.

Special Scheme of Study for Industrial Fatigue

VARIATIONS IN INDUSTRIAL CONDITIONS

Conditions of the workplace	*Conditions of the workers*
Hours and intensity of work	Type of worker employed
Type and method of work	Vocational selection
Physical environment. air, light, noise, etc.	Training and experience of workers
Social and psychological environment:	Wages and living conditions
Supervision and relations within working groups.	
Methods of wage payment, etc.	

CAUSE

VARIATIONS IN THE 'HUMAN FACTOR'

INDICATED BY

Output	*Accidents*	*Lost time*	*Labour*	*Efficiency*
Quantity Quality Economy		(Absenteeism)	Turnover	(Performance tests)

The typical unit investigation consists in keeping a group of workers under observation and determining the form and degree of correlation (or 'co-variation') between measured variations in any one condition, and measured variations in an index test of their efficiency, for example, the law of co-variation between a group's hours of labour and their quantity of output or between temperature of the air and a group's accidents. In any actual situation many variable but uncontrollable circumstances arise, of course, during the period of observation. For this reason these studies were social not only in observing a society such as a factory, but also in depending for the reliability of their conclusions upon a statistical norm for a *whole social group* in which individual deviations cancelled out. They were social not only by choice of subject but also by sheer methodological necessity.

To obtain exact statistical norms both conditions and tests of efficiency had to be numerically measurable, and much of the methodology involved consisted in establishing quantitative indexes. Most of the tests of human efficiency are now standard ratios; even quality and economy of output can be reduced in many cases to percentages of spoilage and wastage. But many of the industrial conditions are harder to measure. Type of occupation, for example, did not at first sight appear capable of statistical assessment. But a preliminary qualitative analysis disclosed quantitatively measurable variables such as length of required training, the frequency of repetitions, regularity of repetition (or rhythm) measured by a low deviation from average in the times of successive repetitions of a job[3]. Social relations and environment are obviously the least easy to reduce to a measure. But the work of Prof. Mayo of Harvard and his collaborators at the Western Electric's Chicago works has shown how much of the overt behaviour of groups of workers can be objectively observed and numerically recorded[4]. Clearly, further research using quantitative methods is urgently needed in the social psychology and anthropology of industrial groups.

Once a statistical co-variation is established, it remains to interpret the precise chain of causation. In my industrial studies I used as a working hypothesis a 'human factor', variations in which were taken (1) to cause variations in the tests of efficiency, (2) to be caused by variations in the industrial conditions[5]. The precise psycho-physiological processes such as fatigue that may be manifested by this human factor, intermediate between conditions and tests, is largely a matter for clinical and laboratory study. This was the point in the scheme where external observations, accurately measured and summarized statistically, gave place to 'internal' experiment and analysis. Such experiment often artificially reproduced the industrial situation in a laboratory. It attempted to test some particular variation in the human factor under conditions deliberately selected and controlled.

2. Application to Social Medicine

The study of industrial fatigue, defined broadly as a study of the variation in human efficiency associated with variations in industrial conditions, is unquestionably a special branch of social medicine, and it is possible that the technique specially developed there may prove useful to social medicine in general. Tentatively I suggest the following enlarged general scheme, which would make the definition of social medicine *the study of the variations in human health and efficiency associated with variations in social conditions*.

General Scheme of Study for Social Medicine

VARIATIONS IN SOCIAL CONDITIONS

(*A*) Occupations	(*B*) Living Conditions	(*C*) Persons Affected
	Home Life	
School or work, if any	(determined largely by income)	
Hours and intensity of occupation	Food	Sex, age, condition (e.g., motherhood)
Physical conditions	Housing	Heredity (physical and mental)
Social and psychological environment	Distance from work	Acquired characters
Type of occupation	Degree of urbanization	Education
Unemployment	Medical attention	Vocational training
	Family relations	Background and experience
	Recreation	
	Community Services	
	(determined largely by central and local government expenditure)	
	Public hygiene, hospitals, insurance, etc.	

CAUSE

VARIATIONS IN PSYCHO-PHYSIOLOGICAL MECHANISM

(*'Deviations from Positive Health'*)

INDICATED BY

Marriage, Fertility and reproduction-rates	Measurement of physique	Morbidity (various diseases)	Mortality (various diseases)	Efficiency records (output, accidents, etc.) and tests
1	2	3	4	5

All the working conditions on the left-hand side of the special industrial fatigue scheme are here grouped under occupation, which may apply to *school* or *work*, either in industry or in the Forces. The effect of unemployment must also be considered. Living condi-

tions take on an increased importance and are given a column to themselves. They may be divided into home life, including the food still customarily taken there, and community services. These services may be preventive, such as are rendered by local medical health officers, curative such as the hospital services, or palliative such as insurance benefits.

In the investigation of industrial fatigue, type and training of workers and their selection to fit their job were found to be important conditions of efficiency (and happiness). It was found to make a difference in the results of, say, hours upon accidents if the workers were men or women, or were experienced or 'green'. Similarly, in any investigation of social conditions it will make a difference on what persons or group of persons the impact of the purely environmental condition falls. As an expansion of 'type' and 'training' of workers a third column is therefore added to the general scheme of study, headed "Persons Affected". Here the influence of nature and nurture (sex, age, heredity, education, experience) upon differences and variations in human health and efficiency and their importance in recruitment of personnel is taken into account. This is the special field of social biology, and its importance suggests that a fully developed school of social medicine should have a special lecturer or readership in social biology attached to the chair.

The indexes and tests of efficiency in the original scheme may be enlarged by the addition of standardized tests of health and survival such as marriage, reproduction and fertility-rates, morbidity and mortality-rates from various causes, and in general. There will, of course, be the same need for laboratory and clinical research into the intermediate psycho-physiological mechanism to interpret how the variable social conditions are associated with variations in these statistically measured external events. One approach, already mooted, is to assume psycho-physiological variations or deviations from some standard of *positive health*.

Many of the social conditions are now directly measurable in statistics already recorded or easily reckoned: under the heading occupation, hours worked and physical conditions; under the heading home life, physical housing conditions, distance from work, degree of urbanization (by population density), family income (largely determining food consumption); under community services, per capita expenditure of central and local authorities; under persons affected, age, period spent at school or in training. The possibilities and limits of such exact information both about social conditions and tests of health and efficiency require a lecturer or readership in demography and social statistics for their elucidation.

Where statistical records are not yet available in sufficient detail or do not answer the relevant question, *ad hoc* inquiries should be made in the field. For example, the constituents of food purchased or eaten by families, the actual extent of specific types of social services performed, the stop watch measurement of the intensity of work, social relations both at the place of occupation and in the home and community. The need mentioned above for exact psychological and anthropological study extends from industrial to all other social groups. Social medicine would indeed be greatly helped by the establishment of lecturers or readerships enabling fieldwork observations to be undertaken in the social psychology or anthropology of factories, schools or indeed typical households. The hospital almoner, for example, constantly comes up against 'case work' problems arising from psychological reactions to work or to family relationships, and needs expert advice. Much of the research work here would be preparatory to statistical measurement. The quality of types of social relationships must be understood before quantitative assessment of each type can be undertaken.

Classical and recent research in social medicine may be briefly reviewed (giving references in brackets) to show how far the lines actually developed fit into the scheme of study outlined above. If occupation (at work or school) and living conditions be lettered A and B, and the five tests of health and efficiency numbered 1, 2, 3, 4 and 5, we can find examples of all possible combinations of variation in one sort of condition A or B with variation in tests 1 to 5. Besides these 'couplings' there are 'triplings', 'quadruplings', and so on, where variations in two or more sorts of condition are related to a test. It is here that the persons affected (column C) come into the picture as influencing the effects of the purely environmental conditions.

Couplings	*All possible combinations*
A and 1	Differential Fertility of Different Occupations (Dr. Enid Charles)
A and 2	Measurements of Height, Weight, Muscular Strength, etc., of Unemployed. (Industrial Health Research Board)
A and 3	Relation of Type of Work to Sickness Absence. (Medical Research Council)
A and 4	Occupational Mortality-Rates. (Registrar-General)
A and 5	Hours of Work and Output, Absenteeism, Accidents, etc. (Health of Munitions Workers Committee) (U.S. Public Health Service)
B and 1	Differential Fertility of Income Classes, Rural and Urban Populations. (Dr. Enid Charles)
B and 2.	Food and Malnutrition Symptoms. (Sir John Orr)
B and 3	Ante-Natal Services and Maternal Mortality. (Ministry of Health (Report 1937))
B and 4	Density of Population and Death-Rates. (Dr. Farr)
B and 5.	Wages and Output. "The Economy of High Wages". (Lord Brassey)

Triplings, etc.	*Scattered Examples*
BC and 4	Infant Mortality by Income Class. (Registrar-General)
AC and 5	Accident Proneness in Factories. (Industrial Health Research Board)
ABC and 5	Retardation of School-children and Poor Homes. (Lloyd and Burt, City of Birmingham)

3. Summary and Conclusions

1. If social medicine is defined as the study of variations in human health and efficiency associated with variations in social living and working conditions, it can be viewed as an extension of studies of industrial fatigue initiated before the War of 1914–18.

2. Such studies, aiming at the scientific observation of social norms of behaviour, can and (where laboratory experiment is impossible) must be based on statistical measurement and summarization. They require full exploration of the possibilities of vital statistics as a measure of health and efficiency as well as statistics of social conditions. A professor of social medicine should have the co-operation of a reader in demography.

3. The social conditions the observation and measurement of which have proved particularly difficult in fatigue studies, and are likely to do so in social medicine, are those relating to psychological social and family relationships. Readerships in social psychology and anthropology would clear up many of the more difficult obstacles in the path of social medicine.

4. Different classes of persons will react differently to similar conditions according to their heredity, sex, age, education and past experience. Such variation due to nature and nurture (apart from present environment) must be studied in a social biology, for which additional provision should be made.

5. A chair of social medicine should thus, in a fully developed school, be supported by a staff that includes experts in demography and social statistics, in social psychology and anthropology, and in social biology.

STRUCTURE OF HETEROCHROMATIN

By DR. G. PONTECORVO
Department of Zoology, University of Glasgow

IT has long been known that some chromosomes, or chromosome segments, respond to staining during mitosis or meiosis in a different way from the rest of the set. They are called 'heterochromatic' to distinguish them from the 'euchromatic' rest of the set taken as a standard. The cyclic staining reaction of the chromosomes is generally attributed to synthesis, during prophase, and breakdown, during telophase, of desoxyribose nucleic acids—a view recently challenged by Stedman and Stedman[1], but which will be followed here, the substance actually involved being irrelevant for the present discussion. It is now clear, especially from the work of Darlington[2] and his collaborators, that the visible difference between heterochromatin and euchromatin is a consequence of a difference—referred to as 'allocycly'[3]—in the timing and/or in the amplitude of the above cycle. In heterochromatin the maximum nucleic acid charge attained by euchromatin at metaphase may be attained earlier, later, never or even surpassed. This behaviour has been taken as showing that heterochromatin has a lower reactivity in nucleic acid synthesis, and that, therefore, only when the demand for nucleic acid precursors by the more active euchromatin is low can heterochromatin successfully compete for them. It will be seen that another explanation is also possible.

Let us consider the characteristics and behaviour of heterochromatic segments. In the first place, the same segment, or chromosome, may be visibly allocyclic in one tissue and not in another, or it may have different allocyclic behaviour in different tissues. An example of the former type are the sex-chromosomes of many mammals, strongly allocyclic at meiosis but not so at mitosis; and of the latter the *X*-chromosome of the Acrididæ, in which the cycle is shifted one way in certain divisions of the germ track and the opposite way in others[4]. Thus the allocyclic behaviour is determined by at least two factors: the reactivity of the heterochromatic segment itself and the conditions of the cell[3]. As some of the latter can be controlled, what happens in Nature between tissues has been imitated experimentally within one tissue. For example, by low-temperature treatment it has been possible to detect as heterochromatic in mitotic or meiotic metaphase segments that under normal conditions could not be identified as such[3,5].

Secondly, two or more heterochromatic segments in the same nucleus, or even in the same chromosome, often differ from each other, besides differing from euchromatin, in their nucleic acid cycle. A conspicuous example of this is provided by the pairing and differential segments of mammalian sex-chromosomes: both are heterochromatic but with distinct cycles[6]. In this case it is certain that the different cycle goes with different genetical properties.

Thirdly, heterochromatic segments, or chromosomes, have been identified of any visible length. They may be located in any part of the chromosome set. Of course, the greater their length and the stronger their allocycly, the more easily they are detected. Our knowledge of their occurrence in animals and plants is, thus, inevitably a very distorted one.

Fourthly, certain heterochromatic segments in some species have the property of 'non-homologous' association in the prophase of meiosis, or in the polytene chromosomes. This property, however, is of erratic occurrence and tends to occur in groups of related species, rather than at random. This suggests a common origin for a property that, as will be seen later, is by no means a general characteristic of all heterochromatin.

Finally, since the discovery by Muller and Painter[7] of genetically 'inert' chromosome segments, and their identification by Heitz[8] with heterochromatic segments, 'inertness' has been found to accompany allocycly in all unambiguous cases. This 'inertness' manifests itself in two ways. One is that, per unit length, heterochromatic segments carry fewer, or no, genes detectable by sharply alternative effects of different allelomorphs. The other is that deficiencies or duplications for heterochromatic segments have far less harmful effects than deficiencies or duplications for euchromatic segments of the same size. The 'inertness' of heterochromatin may mean that either there are actually few, or no, genes in it, or there are a full quota of genes but the developmental effects of mutation or change in quantity in them are difficult to detect. Recent work[11,12,13,14,15] strongly suggests that the latter alternative is the correct one.

Several trends of thought and lines of research seem to agree in regarding heterochromatin as internally less differentiated than euchromatin. Indeed, this idea was already implicit in Muller's early suggestion that what we now know as heterochromatin originates from mutation towards 'inertness' of genes kept in a permanently heterozygous state, as those of the *Y*-chromosomes. Caspersson[9] and his collaborators consider heterochromatin as "built up of identical or similar elements or genes", a construction that would explain why deficiencies or duplications are so much less harmful than for comparable euchromatic segments. Furthermore, they consider that the greater uniformity of heterochromatin is expressed in the simpler types of proteins which, by means of ultra-violet spectroscopy on salivary gland chromosomes, they found in it. Unfortunately, as the same authors have shown, the types of proteins in the chromosomes change during successive stages of the division cycle, and Painter[10] has discovered that the salivary gland chromosomes undergo a process somewhat comparable to that of mitosis. As heterochromatin and euchromatin have cycles that may not coincide in time, only a comparison covering whole cycles in the same types of cells, and in different species, could show whether the difference in the types of proteins is general and not spurious. Darlington[2] has expressed the idea of the lesser internal differentiation of heterochromatin by saying that the difference between 'activity' (of euchromatin) and 'inertness' (of heterochromatin) is a difference between high

specificity and low specificity. Further, with his collaborators[11,12,26], he has shown that the heterochromatic 'supernumerary' chromosomes, characteristic of many animals and plants, are by no means inert. These 'supernumeraries', though varying in number between cells of an individual and individuals in a population, tend, as noted by Slack[13] in Cimex, towards an equilibrium, which Darlington and his collaborators have shown to be adaptive. Finally, Mather[14,15] has given a concrete expression to the view of the uniform structure of heterochromatin by suggesting that heterochromatin is made up of 'polygenes', and by finding genetical evidence which supports this idea. Study of the genetical and cytological properties of mammalian sex-chromosomes[6] also supports Mather's view.

There seems to be, in conclusion, a considerable amount of agreement for considering heterochromatin as internally less differentiated than euchromatin. On two points, however, the present trend of thought is not equally definite. One is the connexion between this lesser differentiation and the allocyclic behaviour. The other is the question of whether or not the elements that make up heterochromatin are necessarily different from those that make up euchromatin. These two questions will now be discussed.

Let us first consider what makes the nucleic acid cycle of euchromatic regions appear uniform throughout the nucleus. It is proper to raise this question before discussing what makes heterochromatin differ in this respect, because, in fact, during a brief part of the division cycle euchromatic regions are far from uniform along their length. This part is early prophase, especially of meiosis, when nucleic acid has already condensed along the chromosomes but their lengthwise contraction is barely starting. In this short period the chromomeres are distinctly visible and obviously differ from each other in their nucleic acid charge. Each chromomere shows a distinct reactivity of its own in nucleic acid synthesis; it is 'allocyclic' in relation to others, either because its cycle is shifted in time, relative to that of other chromomeres, or because different chromomeres synthesize at different rates or reach different final charges. The giant salivary gland chromosomes of Diptera show this longitudinal differentiation of euchromatic regions even better: their 'bands' present an array of different charges and are intermingled along the chromosomes more or less at random with respect to these charges. As mitosis or meiosis proceeds, the chromosomes contract enormously by spiralization and loss of proteins[9]. Consequently it is no longer possible to distinguish the individual chromomere; all that a chromosome segment can show is the aggregate effect of its component chromomeres. In segments with intermingled chromomeres of different charges, the result is apparently uniform within and between segments. The reaction of euchromatic regions, optically uniform as they are after prophase throughout the whole chromosome set, is, thus, the statistical consequence of their being made up of a mixture of highly differentiated chromomeres. The immediate corollary is that a segment in which chromomeres are more uniform may differ in its aggregate reaction from the former.

If we accept the view that heterochromatin is made up of elements less differentiated than euchromatin, we have only to assume that these elements are chromomeres, and chromomeres of the same type as those which we find intermingled in euchromatin. The essential difference between the two types of chromatin would then lie exclusively in the linear arrangement of chromomeres with the same nucleic acid cycle: a heterochromatic segment being one with a very high proportion of these similar or identical chromomeres. Segments made up of repeated replicas of a single type-chromomere, or few type-chromomeres, would be the extreme term in a series between euchromatin and heterochromatin. Unfortunately, the only case in which, so far, it has been possible to make out the minute structure of heterochromatin in a suitable stage is that of some Dipteran salivary chromosomes. Here each heterochromatic segment actually consists of chromomeres far more uniform than those of the euchromatin; moreover, in Drosophila, some, but not all, heterochromatic segments in a salivary gland nucleus agree in having the same types of chromomeres[16]. The latter feature, however, like that of 'non-homologous' association probably connected with it, is certainly not general.

Clearly the preceding suggestion accounts for the allocyclic behaviour of heterochromatin. In fact, the nucleic acid cycle of the type-chromomere, or chromomeres, making up a heterochromatic segment, will but seldom happen to be identical with the nucleic acid cycle of euchromatin, which is an average. More often it will be distinct, being out of phase or in other ways differing from the latter, just as two 'euchromatic' chromomeres may differ from each other. Furthermore, the type-chromomere, or chromomeres, of each heterochromatic segment need not, and often will not, be the same for different segments, thus accounting for the different allocyclic behaviour of two or more segments in a nucleus. On the other hand, it may be inferred that 'non-homologous pairing' occurs just in those species where these type-chromomeres happen to be the same in more than one segment; in other words, in cases where two or more heterochromatic segments have a common origin, as Prokovjeva[17] and Muller[18] suggest for Drosophila. This would also explain why this property appears erratically but tends to occur in several of a group of related species. Thus allocyclic behaviour can be accounted for by assuming a different linear arrangement of similar chromomeres without need of the further assumption of any difference in the nature of the chromomeres themselves. Can we, on this simple assumption, also account for the functions in cell physiology that are being attributed to heterochromatin?

The main inference is that heterochromatin acts as a regulator of the nucleoprotein metabolism of the cell and therefore controls the reproduction of the chromosomes[2,9,11,19,20]. This function is deduced mainly from consideration of the activity of the nucleolus, and of the disturbances arising in the division of the nucleus as a whole in consequence of excess or defect of heterochromatin, and in the division of parts of the chromosomes in consequence of changes in the relative position of eu- and heterochromatin. Indeed, the weight of part of this evidence would become decisive only if it were established that euchromatin does *not* produce the same effects. However, on the basis of the structure of heterochromatin as proposed here, one would expect each heterochromatic segment to exercise both a localized and a general *specific* effect on the conditions of nucleoprotein synthesis in the nucleus, often different from the *non-specific* effect (in this respect) of any euchromatic segment of comparable length. It is, therefore, permissible to venture a prediction:

namely, that close investigation will reveal very characteristic differences in the action of different heterochromatic segments in the same species, and between species. It is perhaps due to the fact that so much use has been made of Drosophila for the investigation of heterochromatin that this possibility has been overlooked (but see Demerec[27]).

This brings us to speculate upon the origin of heterochromatin. It is implicit in the view expressed here that a heterochromatic segment should arise every time that a minute euchromatic region undergoes repeated reduplications in the genotype and the replicas remain adjacent to each other on the chromosome. Models of some such process are known, and there is every reason to believe that, once a first replica has become established, the mechanical and genetical possibilities of its being repeated are enhanced. The finding by Harland[21] that the same function may be performed in one species by a single gene and in a related species by many is perhaps an example of the genetical consequences of this process. There is, thus, plenty of scope for new heterochromatic blocks to be formed, for old ones to be eliminated, and for variations in size. Furthermore, inversions and other appropriate structural changes may break up an originally compact heterochromatic segment into many small ones interspersed among euchromatin (cf. Kaufmann[22]). Natural selection and accidental variation seem to have a number of possibilities here.

As stressed by Wharton[23] and by White[24], among others, heterochromatin certainly plays an important part in speciation. This part stands out in terms of Mather's[25] theory of polygenic variation. Mather has studied the function of linkage between 'polygenes' (definable perhaps as genes existing in repeated replicas in the genotype) as a basis on which the evolutionary plasticity of a species is founded; he has now reached the conclusion that heterochromatin is made up of polygenes[15]. We see that the formation of new heterochromatic segments, their loss or dispersion and their variation, by the process adumbrated above, are all mechanisms whereby polygenes may arise and linkage between them may be created and varied.

WORDSWORTH AND SCIENCE

By DR. V. B. WIGGLESWORTH, F.R.S.

To the solid ground
Of nature trusts the Mind that builds for aye;
Convinced that there, there only, she can lay
Secure foundations.

FOR seventy-five years the first lines of this quotation have appeared on the cover of NATURE. For long enough the quotation was inaccurate; not until 1929 and 1934 were the errors brought to the notice of the Editor and put right. When the lines first appeared in this setting, Wordsworth had been dead for nearly twenty years. Had he been alive he could scarcely have approved the use to which his words were put. To the scientific reader of NATURE (after he has permitted himself perhaps a fleeting smile at the *double entendre*) the words may well convey a sentiment gratifying to his self-esteem. But there is little in the sonnet from which they are taken to justify that feeling, and less in Wordsworth's writings as a whole.

In a moment of enthusiasm in 1833, writing of "Steamboats, Viaducts and Railways", Wordsworth cries:

Nature doth embrace
Her lawful offspring in Man's art; and Time,
Pleased with your triumphs o'er his brother Space,
Accepts from your bold hands the proffered crown
Of hope . . .

By 1844, when the railway threatens Kendal and Windermere, the tone has changed:

Is then no nook of English ground secure
From rash assault?

He "scorns a false utilitarian lure".

But it is Wordsworth's abstract reflections on science, when writing at the height of his powers, that we shall take more seriously. His attitude to science is almost uniformly hostile. "All *heaven-born* instincts shun the touch of vulgar sense." In 1806 he writes of the "Star-gazers", the public in Leicester Square who, for the price of one penny, are permitted to glimpse the heavens through a telescope. It is a parable on the ultimate dissatisfaction of those who "pry and pore". The same feelings about science find their most unbridled expression in "A Poet's Epitaph" (1799), where men of many sorts in turn approach the poet's grave. The man of science is greeted thus:

Physician art thou?—one, all eyes,
Philosopher! a fingering slave,
One that would peep and botanise
Upon his mother's grave?

He is besought to take his "ever-dwindling soul, away!"

A more considered variant on this recurrent theme is to be found in Book IV of "The Excursion" (1810–20). Shall those "ambitious spirits" who "have solved the elements, or analysed the thinking principle . . . prove a degraded Race?"—"Oh! there is laughter at their work in heaven!"

. . . go, demand
Of mighty Nature, if 'twas ever meant
That we should pry far off yet be unraised;
That we should pore, and dwindle as we pore,

Viewing all objects unremittingly
In disconnection dead and spiritless ;
And still dividing, and dividing still,
Break down all grandeur . . .
. . . And if indeed there be
An all-pervading Spirit, upon whom
Our dark foundations rest, could he design
That this magnificient effect of power,
The earth we tread, the sky that we behold
By day, and all the pomp which night reveals ;
That these—and that superior mystery
Our vital frame, so fearfully devised,
And the dread soul within it—should exist
Only to be examined, pondered, searched,
Probed, vexed, and criticised ?

His spirit revolts at the ways of men of science, who prize the human soul and the transcendent universe

No more than as a mirror that reflects
To proud Self-love her own intelligence.

In one passage only, of which I am aware, and that still later in "The Excursion", does Wordsworth admit that science may find "its most noble use . . . in furnishing clear guidance to the mind's *excursive* power" and "then, and only then, be worthy of her name":

For then her heart shall kindle ; her dull eye,
Dull and inanimate, no more shall hang
Chained to its object in brute slavery.

Ought we then:

To reinstate wild Fancy, would we hide
Truths whose thick veil Science has drawn aside ?

No ! No matter how high we rate "the thirst that wrought man's fall" . . . "the universe is infinitely wide" and reason will ever meet "some new wall or gulf of mystery" which nothing but "Imaginative Faith" can overleap.

The fact is that Nature for Wordsworth has so deep a meaning.

The sounding cataract
Haunted me like a passion : the tall rock,
The mountain, and the deep and gloomy wood,
Their colours and their forms, were then to me
An appetite.

Perhaps that is as far as most votaries of Nature get. But in these lines Wordsworth, "so long a worshipper of Nature" (and if Wordsworth says "worshipper" he means it) is looking back to his "thoughtless youth" before he had learned to hear in Nature "the still sad music of humanity" and had gained "a sense sublime of something far more deeply interfused . . .", the "soul of all my moral being". Indeed, he goes on almost to reproach his sister that "in the shooting lights" of her "wild eyes" he can read only those more superficial joys. She lacked as yet:

. . . the spirit of religious love
In which I walked with Nature.

It is true that, for a time, depressed and bewildered by the excesses of the Revolution in France and the reactions it provoked, he "turned to abstract science" and there sought

Work for the reasoning faculty enthroned
Where the disturbances of space and time,
. . . find no admission.

But he was soon recalled by Dorothy and "preserved a Poet" to "seek beneath that name alone" his "office upon earth" and to derive "genuine knowledge" from "sweet counsels between head and heart".

Such is a fair picture of Wordsworth's view of science. Whether the poet would have deemed it an act of piety to con and sift his writings in this way, to the sorry detriment of his grand use of words, is open to doubt. He might well have cried :

Our meddling intellect
Mis-shapes the beauteous forms of things :—
We murder to dissect.

To-day, when physics ends in the mists of mysticism, it may be that science might claim kinship with Wordsworth the poet. But science now claims all society as her province, and Wordsworth the prophet and reformer would fit less awkwardly into the pages of NATURE. The Wordsworth who, standing at the threshold of the Industrial Revolution, with a mind not warped by politics, can compare with truly scientific objectivity, though with all a poet's feeling, the evil of the factory child with the grinding penury of rural England and the ignorance and degradation of the children on the land. The Wordsworth who can describe the factories wherein "little children, boys and girls" enter and

where is offered up
To Gain, the master idol of the realm,
Perpetual sacrifice,

and who can yet rejoice

(Measuring the force of those gigantic powers
That, by the thinking mind, have been compelled
To serve the will of feeble-bodied Man)

in the conviction that late or soon man will learn that "physical science is unable to support itself" and that

. . . all true glory rests,
All praise, all safety, and all happiness
Upon the moral law.

The Wordsworth who, surveying all these evils present and to come, finds a solution and a hope (this in 1810) in "a System of National Education established universally by Government" and urges that such a system be begun at once even "when oppression, like the Egyptian plague of darkness" is "stretched o'er guilty Europe". For then

Change wide, and deep, and silently performed,
This Land shall witness.

OBITUARIES

Mr. J. Reid Moir, F.R.S.

I FIRST met Reid Moir so long ago as 1911. Rumours had been flying about that it had been demonstrated without cavil that the Garden of Eden had been close to Ipswich, that mankind's birthday had been thrown back millions of years, that the 'missing link' had been at last found ; that all these startling new discoveries were the result of a Mr. Moir's finds in a gravel pit near Ipswich. The facts were that Moir, in business in Ipswich, instead of playing golf in his spare time, spent all his leisure in the gravel pits near his home in the hope of discovering the relics of

early man. In this he was helped and backed up by the late Sir Ray Lankester, without whose aid even Reid Moir might have failed to 'get his ideas over'. The age of the gravels in question has never been doubted. They contain a rich fauna and belong to a period *antedating* the Cromer Forest bed : in the still current nomenclature they are late Pliocene in date. Moir claimed that *in situ* in these gravels he had found artefacts, that is, flints which had been chipped by man, and which for reasons given could not have been the result of natural operations.

The heat of the controversy which at once burst on Moir's head can only be explained if we remember that theological as well as archæological considerations were involved. The theory of evolution as outlined by Darwin had, it is true, been somewhat grudgingly accepted by the Churches; but here was a little business man in a provincial town who ventured to throw back the antiquity of man to some incredible date, to throw completely out of balance the accepted order of man's history. On no other ground can one explain the fury of the conflict. One of Moir's opponents actually had printed in colour a Christmas card burlesquing the whole theory. But Moir was of Scottish origin and had been hardly brought up by his father, the founder of the tailoring business he was later to inherit. Indeed, he once told me that at first he was made to sweep out the premises in the morning. He just persisted in his theories, collected more and more evidence from the pits, and studied more and more closely the complicated phenomena of flint fracture. Through thick and thin he continued to have the support of Lankester and a small number of scientific men with open minds.

But it was not until 1920 that the great moment came. It must be remembered that prehistory was recognized as a definite subject much earlier on the Continent—more especially in France—than in Great Britain. The two chief exponents there were Profs. Boule and Breuil. Both had written long articles against Moir's ideas. One based his objections on observations of a mortar-making machine at Mantes, the other on some finds of flints flaked as a result of earth pressure. It was in 1920 that Moir discovered certain chipped flints which seemed to him conclusive, and he sent them to the Sedgwick Museum at Cambridge for consideration. The late Prof. J. Marr called me in for consultation and as a result I invited the Abbé Breuil to come to Cambridge at once, which he did. I took him over to Ipswich, and a long afternoon was spent poring over the finds spread out over the floor of Moir's study. Breuil said little, and when driving back in the evening he was still more silent. Then he quietly remarked, "Mon cher ami, aujourd'hui a beaucoup vieilli l'humanité". It was a magic moment ! In the following year he announced his change of ideas at an international congress held at Liège. That each and all of the specimens Moir claimed as humanly fashioned were really artefacts may be doubted : that tool-making animals, almost certainly therefore primitive humans, existed at that remote period is, however, a fact accepted to-day by the vast majority of prehistorians. This is Moir's great work, for which he was eventually awarded a fellowship of the Royal Society.

It would take too long to describe in detail all the investigations Reid Moir undertook in the Ipswich district and elsewhere. Some proved to be important and the results were accepted by the scientific world ; others proved less so, and the explanations put forward at the time had later to be modified. But this is true for any active investigator in the field. Moir was generous with the specimens found in the course of his excavations, and these are now widely distributed in the museums of England and France ; but his first loyalty was to the well-known Ipswich Museum, of which he was the godfather, having, in fact, made it what it is to-day. At the time of his death, he had been studying certain finds made long ago in the Puy Courny district of France. It is to be hoped that his notes are extant. The drawings were already made some considerable time ago ; but the War stopped all idea of publication on a scale necessary for such a work.

Moir was interested in many things besides prehistory, and I have letters of his philosophizing on life generally. He had a soft heart and was much concerned that the slaughter of animals for food should be painless. Indeed, he inaugurated a local campaign to this end. To gain time for his many scientific commitments and interests, he turned his business into a company and as such it did not prosper too well. In fact Moir, in the latter part of his life, was an exceedingly poor man as a result of his scientific toil. He was interested in water geology and took this matter up professionally to some extent. As was to be expected, Moir in his younger days in the heat of controversy could be fierce. I have had letters from him which I promptly burnt ! Nevertheless, his characteristic and ferocious brand of language was part of his robust personality, which never shirked a challenge, and indeed helped to endear him to many of us. But there was a lovable strain right through him, and this, together with his charm of manner, in later years took a more and more prominent place in his nature. I can only add that personally I had a real affection for Reid Moir and sincere regrets that he has gone. This emotion, I am convinced, will be shared by everyone who knew him well. Miles C. Burkitt.

Dr. L. H. Baekeland

In the passing of Dr. Leo H. Baekeland on February 23 in his eighty-first year, the world of applied science has lost an outstanding man. He was an individual of outstanding character with a high moral status and charming personality. One never tired of hearing his stories of his adventures connected with his travels to most lands and his yachting experiences. He lived to see and to gain the benefit of his two great developments, namely, 'Velox' gaslight paper and 'Bakelite' synthetic resins. Of late years he had been in failing health, and the chemical and technical societies of the United States and Great Britain have missed his presence at their annual meetings for about eight years.

Baekeland was born in Ghent on November 14, 1863. He studied science in the University of his birthplace, making chemistry his chief subject, and afterwards became a lecturer in the University. In 1884 he graduated as a doctor of science at the University of Ghent. Although he was not yet twenty years of age he became professor and taught chemistry at the University from 1882 until 1889, and during 1885–89 he taught both chemistry and physics at the State College of Science, Bruges. During this period he also went to Germany, meeting German men of science and learning their language.

He married Miss Celine Swarts, the daughter of

his professor of chemistry, in 1889, and at the end of the same year he emigrated to the United States of America.

In the United States Baekeland devoted the earlier part of his career to research work which resulted in his discovering a process for the production of photographic printing paper, suitable for use in artificial light. To these papers he gave the name 'Velox', which printing paper is still well known throughout the world. In 1893 he founded the Nepera Chemical Co., and in 1898 he sold his interest to the Eastman Kodak Co.

Afterwards, at the age of thirty-five, he returned to research work in a laboratory in a house at Yonkers, near New York, where he worked on various chemical problems, including those connected with resinous products, and made a study of the reaction between phenol and formaldehyde. In 1907 his United States patent on the process for producing phenolformaldehyde resins under control was filed, and this patent became world-famous. In 1909 he read a paper on "The Synthesis, Constitution and Uses of Bakelite" before the New York Section of the American Chemical Society, in which he described in considerable detail the researches which led up to this patent.

In 1910 the Bakelite Gesellschaft was founded in Germany; six months later the General Bakelite Company of America was founded, both companies being for the large-scale production of phenolic resinous materials, known as 'Bakelite' materials. The latter company with the Redmanol Chemical Products Co. and the Condensite Co. of America was afterwards merged into the Bakelite Corporation, of which Dr. Baekeland was the president in 1922.

It was due to Dr. Baekeland's fine personality, initiative and far-sightedness that Bakelite Ltd. in England was formed by an amalgamation of interests which were active in the synthetic resin field.

Many honours were bestowed upon him. He was a commander of the Belgian Order of Leopold, an officer of the Order of the Belgian Crown and an officer of the Order of the French Legion of Honour. For many years he was president of the American Chemical Society. The W. H. Nichols Medal was presented to him in 1909; in 1910 he received the John Scott Medal of the Franklin Institute, and in 1913 he received the Willard Gibbs Medal. When he belonged to the Instruction Board of the Columbia University, he was presented by that University with the Chandler Medal. He was an active member of the Society of Chemical Industry, which in 1916 presented him with the William Perkin Medal of the New York Section of the Society of Chemical Industry. In 1915 he was made a doctor of chemistry *honoris causa* of the University of Pittsburgh. He was also president of the American Institute of Chemical Engineers and of the American Electrochemical Society. In 1938 he was presented with the Messel Medal of the Society of Chemical Industry.

Dr. Baekeland was a member of the U.S. Naval Consulting Board since 1915, a member of the U.S. Nitrate Supply Commission in 1917, and chairman of the Committee on Patents of the National Research Council. He was also a trustee of the Institute of International Education since 1919, and a member of the Advisory Board of the Chemical Division of the U.S. Department of Commerce since 1925.

WE regret to announce the following deaths:

Sir Colin Fraser, director of materials supply of the Australian Department of Munitions and chairman of the Commonwealth Minerals Committee, and a past president of the Australian Institute of Mining and Metallurgy, on March 10, aged sixty-eight.

Prof. A. E. Jolliffe, emeritus professor of mathematics in the University of London King's College, on March 17, aged seventy-three.

Dr. A. W. Pollard, formerly keeper of printed books in the British Museum and honorary secretary of the Bibliographical Society, on March 8, aged eighty-four.

Sir David Prain, C.M.G., C.I.E., F.R.S., lately director of the Royal Botanic Gardens, Kew, on March 16, aged eighty-six.

NEW FELLOWS OF THE ROYAL SOCIETY

THE following were elected fellows of the Royal Society on March 16:

BRIGADIER R. A. BAGNOLD, explorer; distinguished for scientific work on desert topography, and in particular for his precise studies of the physical principles governing the movements and deposition of sand under the action of wind.

MR. R. P. BELL, fellow of Balliol College, Oxford; distinguished for his theoretical and practical contributions to physical chemistry, particularly the studies of reaction rates in solutions, and the applications of wave-mechanics.

DR. C. R. BURCH, research physicist, University of Bristol; distinguished for original research in many branches of applied physics, particularly on the methods for attaining high vacua.

PROF. SUBRAMANYA CHANDRASEKHAR, associate professor in the University of Chicago, formerly fellow of Trinity College, Cambridge; distinguished for his contributions to theoretical astronomy and astrophysics, particularly relating to stellar structure and the dynamics of stellar systems.

MR. G. E. R. DEACON, member of the scientific staff of the "Discovery" Committee of the Colonial Office; distinguished for outstanding work, particularly in the Southern oceans, on physical oceanography and marine zoology, and the relations between them.

SIR JACK DRUMMOND, professor of biochemistry, University College, London, and chief scientific adviser to the Ministry of Food, distinguished for his work on practical nutrition.

DR. A. T. GLENNY, immunologist, Wellcome Physiological Research Laboratories, Beckenham, distinguished for his work on immunity and its application to the immunization of man and animals, especially against diphtheria and tetanus.

DR. R. G. HATTON, director of the Fruit Research Station, East Malling; the pioneer of scientific pomology in Great Britain; the research work which he has organized and directed in this field has a world-wide reputation.

PROF. R. D. HAWORTH, professor of chemistry, University of Sheffield; his contributions to the

structure of natural products are of outstanding importance, and by his synthetical investigations he has added greatly to our knowledge of the lignans.

DR. W. O. KERMACK, research chemist at the Royal College of Physicians, Edinburgh; distinguished especially for his contributions to the knowledge of alkaloids and of synthetic therapeutic compounds; and also for his original contributions to mathematics and statistics in subjects of medical interest.

DR. FRANKLIN KIDD, superintendent of the Low Temperature Research Station, Cambridge; he has made important contributions to the study of respiration of fruits and is well known for his work on the gas storage and low-temperature conservation of apples.

PROF. B. A. MCSWINEY, professor of physiology. St. Thomas's Hospital, University of London: distinguished for his researches on the afferent nerves from the viscera and on the control of visceral movements.

PROF. G. F. MARRIAN, professor of medical chemistry, University of Edinburgh; distinguished for his work in biochemistry, especially on the female sex hormones and related substances.

PROF. M. POLANYI, professor of physical chemistry, University of Manchester; distinguished for his fundamental work on elementary reactions, for his theory of chemical activation energies and for many other important contributions to physics and chemistry.

MR. A. SAND, comparative physiologist, Marine Biological Station, Plymouth; distinguished for his studies of the respiratory mechanisms of invertebrates, the pigmentary effector system of reptiles and the sense organs and locomotor mechanisms in fishes.

SIR WILLIAM STANIER, chief mechanical engineer, L.M.S. Railway, scientific adviser to the Minister of Production; distinguished as a locomotive engineer and particularly for his services in the application of science to mechanical engineering.

DR. C. J. STUBBLEFIELD, senior geologist, Geological Survey of Great Britain; distinguished for his knowledge of the invertebrates of the earlier geological formations; especially for his researches on the life-history, classification and migration of trilobites, and the inter-relationships of graptolites.

DR. O. W. TIEGS, zoologist, University of Melbourne; distinguished for his histological and physiological work; in particular for his studies on the embryology and metamorphosis of insects.

DR. H. J. VAN DER BIJL, director of war supply, Union of South Africa; research physicist; distinguished for his electrical researches, particularly on the conduction of electricity through gases, and for his services with regard to the application of science to industry in South Africa.

MR. J. H. C. WHITEHEAD, University lecturer and fellow of Balliol College, Oxford; distinguished for his varied contributions to pure mathematics, particularly in combinatorial topology, the theory of groups and of group-rings.

NEWS and VIEWS

University of Edinburgh: Chair of Public Health

THE University Court of the University of Edinburgh, in appointing Prof. F. A. E. Crew to the Bruce and John Usher chair of public health, has made an interesting and significant break with tradition. Prof. Crew's association with the University, as teacher and research worker, began in the Department of Zoology and continued in the Institute of Animal Genetics, of which he became the first director in 1921, and the first occupant of the Buchanan chair of animal genetics in 1928. In the Institute he gathered about him a notable band of scientific workers from many nations, and these he inspired with his own enthusiasm, so that a steady stream of the results of research in various directions issued from the laboratories. Prof. Crew's transference from animal genetics to public health indicates a change of outlook in health teaching in relation to the populace. In place of emphasizing, as established courses of instruction have done, aspects of control of infection and the improvement of health by better methods of sanitation and environmental conditions in general, the new outlook, from a biological background, envisages a drive for positive health education backed by tuition in social biology and social medicine.

It is obvious that such development of a biological background in public health education cannot entirely take the place of the detailed knowledge of methods of promoting public sanitation and hygiene, which formed a main part of the established and well-tried course, and of which Prof. P. S. Lelean, who is about to retire from the chair of public health in the University, was so capable and thorough-going an exponent. Advantage has therefore been taken of the excellence of the public health services to enlist their aid, and by arrangement between the University and the Corporation of Edinburgh, the Medical Officer of Health, Dr. W. G. Clark, and the staff of the Public Health Department, will collaborate in that part of the course which deals with the application of science to the control of infectious diseases, to public sanitation and to environmental hygiene. Thus it is hoped to develop a comprehensive curriculum in health and social medicine, to which other specialized departments of university study may make their own individual contributions.

Research Workers in Industry

IN the second of the series of addresses on science and industry to the Manchester Chamber of Commerce, delivered on March 16, Dr. A. P. M. Fleming spoke on "Research Workers: Their Education and Place in Industry". Dr. Fleming pointed out that there are only two broad types of research workers: those engaged in pursuit of knowledge for its own sake; and those engaged in applying new discoveries to useful purposes. The latter bridge the gap between the investigations of the fundamental research worker and industry, and Dr. Fleming stressed the importance of such workers having some industrial experience appropriate to their scientific studies although the training required may differ in different industries. In chemical industry, for example, a post-graduate course in an advanced field of chemistry might be followed for a few years before entering an industrial laboratory. An engineer might be advised to leave the university on graduation and spend a

year or two as an apprentice in an engineering firm with a research organization: when he had thus acquired a knowledge of works organization and the character of its problems, he would proceed to the research laboratory, while if he showed unusual ability for research and special capacity in a particular field, he should return to a university, at home or abroad, where there are special facilities for advanced study in that field. Such plans are only practicable in large organizations with established research facilities, but as an alternative method of training use might be made of the facilities of the research associations, on the lines of the plan developed by the Cotton Research Association, for suitable technically trained men from the industry to spend time in the Association's laboratories and then return to posts in the textile industry. Dr. Fleming remarked in this connexion that the industrial research worker should realize he is something of a missionary and use patience and skill in the application of his work, for it is still difficult in some industries to arouse an appreciation of what science can do to assist the manufacturer.

THE fact that Great Britain is still a country of small manufacturing concerns is a particular difficulty, resulting too often in failure to utilize results already being obtained in research, which the research associations might assist to overcome; though it is important that each small company should have on its staff at least one technically trained officer able to translate and make effective all the appropriate new knowledge provided, for example, by the research association of the industry concerned. While the number of research workers in Great Britain is too small, we can hold our own at all times as regards the quality of research, and Dr. Fleming believes the position is more satisfactory than some of the recent comparisons with research activity in the United States and the U.S.S.R. suggest. Numbers may be more important in the future as industrial problems are undertaken by mass attack, and we must encourage a scientific attitude of mind throughout industry and ensure that our technicians and artisans adopt that attitude of mind and mobility and skill which will enable them to turn new developments to account quickly. Scientific advisers to boards of directors of industrial companies might play an important part, since one of the greatest difficulties in many industries is to get into operation quickly an entirely new type of product for which the existing manufacturing facilities are not fully suited.

Royal Institute of Chemistry

AT the sixty-sixth annual general meeting of the Royal Institute of Chemistry held on March 15, Prof. Alexander Findlay made the formal announcement that the style Royal had been added to the title of Institute. The honour was one which, he said, the Institute accepted for the whole profession. Chemists are proud of what they are able to do in the war effort and no less proud of their achievements in advancing the science of chemistry by research, in promoting industrial prosperity, and in promoting and protecting the health of the people by safeguarding the purity of their food and water supplies and by the production of essential vitamins and drugs. The roll of the Institute has increased during the past year by 462 fellows and associates and by 112 registered students. Representatives of the Institute have served on many bodies dealing with questions of public interest, as well as on those directly affecting the profession of chemistry; with the Joint Council of Professional Scientists consideration has been given to problems which will arise in connexion with the further training and the placing in employment after the War of chemists whose normal careers have been interfered with by national service. Other representatives have taken an active part in the work of the Parliamentary and Scientific Committee, which has published a valuable Memorandum on Research and the Universities.

In the post-war world the calls made on the special knowledge and ability of chemists will be greater even than in the past and, if our industrial prosperity and material welfare are to be ensured, a determined and persistent effort will need to be made by Government Departments, by industry, and by the universities and technical colleges to pull level with our chief industrial rivals. The attitude not only of industrial firms but also of the community as a whole towards science must be changed and the scientific habit and a spirit of trust in science must be cultivated. Prof. Findlay also referred to the Chemistry Education Advisory Board and its report on the education and training of those who enter the profession of chemistry through the secondary schools and the universities (see p. 353 of this issue). The Sir Edward Frankland Medal and Prize for registered students of the Institute has been awarded to Dudley Rhoden Scarffe, of the Imperial College of Science and Technology, for his essay on "Introduction of the Chemist to the Public". Prof. Alexander Findlay was re-elected president of the Institute for the ensuing year.

English Education As It Is

THE Education Bill, the main provisions of which have received considerable attention in NATURE, in anticipation of the parliamentary debates, continues to occupy much public attention. The discussion in the House of Commons drags its slow length along, and on the day when the Bill becomes an Act, everything it provides for will remain to be done. Until that day, and in many respects long after that day, English education is unchanged. It is therefore important that all interested persons should know clearly what most people know more or less vaguely—how precisely it stands with English education in its various stages and phases. For that reason we regard it as a happy inspiration on the part of the Royal Society of Arts to secure the services of Mr. P. R. Morris, director of education for Kent, and now in special charge of army education, to lecture on this subject, under the chairmanship of Mr. R. A. Butler. Very few people have the requisite knowledge and experience and vision to describe exactly the present position in regard to elementary and secondary schools, public and private preparatory schools, and the extraordinary variety of 'the adult stage', and Mr. Morris is one of those people. Perhaps his most valuable contribution lies in what he has to say about the adult stage, including first the universities; secondly, "the field known by the rather dreary name of Further Education"; thirdly, the field now known as adult education, with its great achievements in quality and its "appalling inadequacy in quantity"; and lastly, the institutions for the training of teachers, a major issue in the coming educational revolution. Mr. Morris's paper has been published in full in the December number of the *Journal of the Royal Society of Arts*.

British Council Representative for China

THE British Council has appointed Prof. P. M. Roxby, professor of geography at the University of Liverpool and a specialist on Far Eastern matters, to be its principal representative in China. He will take up his duties in the early part of 1945. Prof. Roxby has visited China on three occasions: during 1912–13 as Albert Kahn Travelling Fellow; during 1921–22 as a member of the China Education Commission; and in 1931 as a member of the British group of the Institute of Pacific Relations. His works on China include "The Far Eastern Question in its Geographical Setting", "China as an Entity: The Comparison with Europe", "The Terrain of Early Chinese Civilisation", "China" (Oxford Pamphlets on World Affairs), and contributions on China in the Encyclopædia Britannica. Prof. Roxby's wife, who is lecturer in history at the University of Liverpool, will accompany him to China. With Prof. Roxby's appointment the British Council hopes to be able to expand its work in China, in co-operation with the Chinese authorities. Many valuable activities are already in progress there, particularly in the scientific field, under the direction of Dr. Joseph Needham, who went out to China for the British Council in October 1942.

Summer Schools in Health Education

THE Central Council for Health Education intends holding two Summer Schools during 1944. One will take place at Whitelands College, Bede College, Durham, during July 24–August 3, and the other at Chelsea Polytechnic, London, during August 9–19. The programme of the schools will cover all aspects of health education (including sex education) and should be of value to teachers, youth leaders, educational and medical administrators, nurses and health visitors, social and industrial welfare workers, etc. The mornings will be devoted to lectures which will lay the necessary foundation of basic knowledge, while the evening lectures will relate this knowledge to a wider philosophical, historical and social context. In the afternoons there will be demonstrations and discussions arranged by the various organizations specializing in different fields of health education, and seminars for students with particular interests. Many applicants had to be rejected from the 1943 School owing to lack of accommodation. Those wishing to receive early notification of the forthcoming schools should send their name and address on a postcard to the Central Council for Health Education, Tavistock House, Tavistock Square, London, W.C.1.

Summer School in Social Biology

THE British Social Hygiene Council will be holding a Summer School in Social Biology at the University College of North Wales, Bangor, during August 19–September 2. The theme of the School will be "Social Biology and the Extra School Year". It is planned to throw light upon the aims and content of biology in the school curriculum, with special reference to the coming increase in the school-leaving age. While primarily intended for those responsible for pupils aged 11–15, the School is designed to appeal to all types of teachers, and to people who are interested in education and social questions generally. The morning instructional lectures will be given by a team of experienced lecturers who have assisted at similar summer schools in the past. The evening meetings will be reserved for the addresses of distinguished scientific and social workers upon the broader applications of biology to human life and culture. In keeping with the lecture programme, demonstrations in practical biology will be arranged to suit the needs of teachers working under school conditions. For those who require it, training in the dissection of common animal types will be given. Times will be set aside for seminars and discussions. Further information can be obtained from the British Social Hygiene Council, Tavistock House South, Tavistock Square, London, W.C.1.

The Night Sky in April

FULL moon occurs on April 8d. 17h. 22m. U.T., and new moon on April 22d. 20h. 43m. The following conjunctions with the moon take place: April 3d. 14h., Jupiter 0·1° S.; April 21d. 11h., Venus 3° N.; April 26d. 12h., Saturn 2° N.; April 28d. 09h., Mars 3° N.; April 30d. 21h., Jupiter 0·4° S. The following occultations of stars brighter than magnitude 6 take place: April 5d. 22h. 26·8m., 308 *B* Leon. (*D*); April 6d. 22h. 51·7m., *b* Virg. (*D*). The times refer to Greenwich and *D* refers to disappearance. Mercury attains its greatest eastern elongation on April 12. The planet sets at 19h. 51m., 20h. 51m. and 19h. 42m. at the beginning, middle and end of the month and can be seen as an evening star, but is not very well placed for observation. Venus rises at 5h. 13m. and 4h. 20m. at the beginning and end of the month and can be seen as a morning star. Mars sets at 1h. 58m. and 1h. at the beginning and end of the month and can be seen in the early part of the night. Jupiter sets at 4h. 10m. and 2h. 15m. at the beginning and end of the month, and is stationary on April 13. Saturn sets at 0h. 46m. and 23h. 04m. at the beginning and end of the month. The Lyrid meteor shower is active from April 18–22. These meteors are due to the debris of Comet Thatcher (1861 i).

Announcements

THE Royal Society, from the income of a fund bequeathed to it by the late Edward Thomas Browne for the support of marine expeditions and of pure marine research work, has placed the sum of £1,000 at the disposal of the Allied Control Commission, to be used in the present emergency for the maintenance of the staff and equipment of the Zoological Station at Naples.

THE Society of the Sigma Xi, the well-known American scientific society, founded at Cornell University in 1886 for the "encouragement of Original Investigation in Science, Pure and Applied", with local members organized as chapters or clubs in some hundred and twenty-five American universities and colleges, is extending its activities to non-academic research institutions which qualify because of their participation in, and encouragement of, original research in science. The first industrial research group to qualify and be granted affiliation with Sigma Xi is the Esso Research Club, of Elizabeth, N.J., the membership of which is drawn from the chemists, physicists, engineers and other technical research and development personnel of the companies associated with Standard Oil Company (N.J.).

ERRATUM.—In NATURE of March 11, p. 319, paragraph on "Meiosis in the Striped Hamster", the number of chromosomes should be $2n = 14$, not $2n = 24$ as printed.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Radioactivity in Osmium

CURRENT theory of the stability of atomic nuclei indicates that two neighbouring isobars, that is, two nuclei with the same mass number and with nuclear charges differing by one unit, should not both be stable, but that the nucleus of higher energy should undergo radioactive change and transform into the other.

There exist, however, five pairs of neighbouring isobars in which both members of the pair are apparently stable. There are two ways in which this may be explained. Either we may assume that the difference of energy between the two nuclei of the pair is too small to allow a radioactive change, that is, to permit the formation of a neutrino, or we must suppose that the radiation which is emitted by one of them has hitherto escaped detection.

The first explanation leads, as Bethe and Bacher[1] have shown, to the result that the mass of the neutrino must be about one fifth of the electronic mass. From other evidence, this seems improbable and consequently the explanation is suspect.

There are three possible types of change: (1) the emission of a negative electron by the nucleus of lower charge; (2) the emission of a positron, or (3) transformation by electron capture of the isobar of higher charge. Bethe and Bacher have pointed out that the first two processes should not be difficult to detect, for the rates of transformation, calculated on the basis of known energy differences between the isobars, should bring them well within the limit of

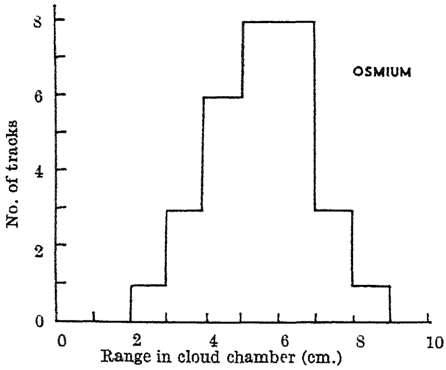

FIG. 1.

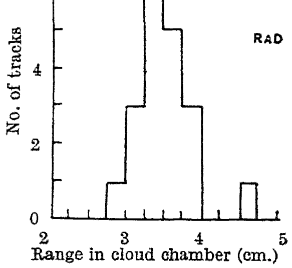

FIG. 2.

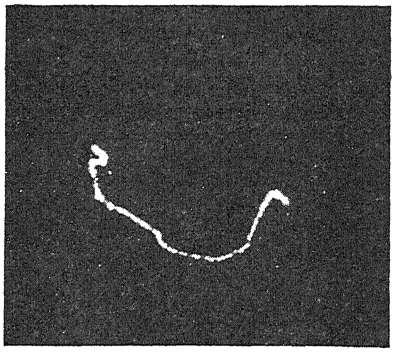

FIG. 3. AN ELECTRON TRACK, 5·1 CM. LONG, RECORDED IN THE CLOUD CHAMBER CONTAINING OSMIUM METAL.

ready observation. It seems, then, that since electron capture would be difficult to detect, process (3) is the most probable explanation of the facts.

A systematic examination of the pairs of neighbouring isobars was begun in this laboratory some time ago; but only in one case, that of osmium, has any definite evidence of transformation been obtained. The osmium isotope of mass 187 (abundance 1·64 per cent) is isobaric with a rhenium isotope (abundance 61·8 per cent), so that on the hypothesis outlined above we might expect a sample of osmium to emit K-radiation of rhenium as a result of the capture of a K-electron. The rhenium K-radiation has an energy of 59 keV. and would give a photo-electron of range about 5 cm. in air. This is convenient for measurement in an expansion chamber; on the other hand, the absorption coefficient of the X-rays is so small (half-value thickness 30 metres in air) that the chance of conversion in the chamber is very small.

A layer of finely divided osmium metal was spread on a tray 20 cm. × 6·5 cm., which was placed in the large expansion chamber described by E. J. Williams[2]. Nearly three hundred photographs were taken, and on these, thirty electron tracks of short range, which started in the gas, were observed. The distribution in range of these tracks is shown in Fig. 1, and it suggests a definite group of electrons of mean range in air, corrected to 15° C. and 760 mm. pressure, of 5·0 ± 0·5 cm. The energy of the electrons was estimated by photographing the photo-electron tracks due to the 47·2 keV. γ-radiation of radium D under similar conditions of operation of the expansion chamber. The distribution of these tracks is shown in Fig. 2, giving them a mean range of 3·0 ± 0·25 cm. in standard air. Assuming that in this region the energy is proportional to the square root of the range[3], this experiment gives an energy for the osmium radiation of 61 ± 6 keV., in good agreement with the energy of the rhenium K-radiation.

With such an extended source it was difficult to assess accurately the half-value period of the activity, but it is possible to make a rough estimate from the geometry and sensitive time of the chamber. The value is 3×10^8 years, but this may be inaccurate by so much as a factor of ten. Attempts, by Dr. J. Rotblat and Mr. D. G. E. Martin, to detect the activity in a Geiger counter were inconclusive and set a lower limit to the half-value period six times greater than the above value. It is interesting to note that Scherrer and Zingg[4] also examined osmium with a Geiger counter and found a small effect which they attributed to impurity.

We wish to thank the Mond Nickel Company, which lent the pure osmium powder.

Banded Meson Spectrum and the Rossi Second Maximum

A VERTICAL counter telescope, designed on the basis of Bhabha's method[1], was set up as shown in Fig. 1. 5·25 cm. of lead used in positions II and III together absorb all but the very high-energy electrons. Such high-energy electrons produce showers in the lead in position II and are cut out from being counted by the shower particles tripping the anti-counters 4 or 5 or both. The effect of side showers on this counter telescope is found experimentally to be negligible[2]. The fact that this arrangement measures the hard component only has also been experimentally verified[2].

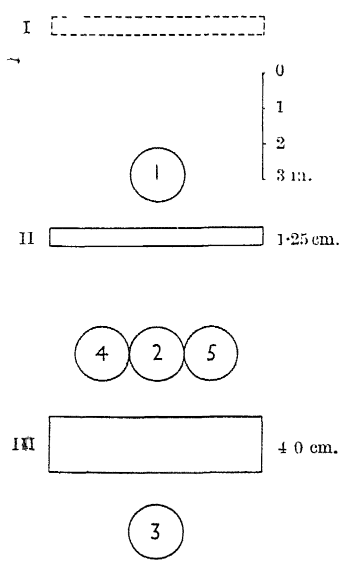

Fig. 1. COUNTERS 1, 2 AND 3 ARE IN COINCIDENCE. COUNTERS 4 AND 5 ARE CONNECTED IN PARALLEL AND IN ANTI-COINCIDENCE WITH COUNTERS 1, 2 AND 3.

The absorption of mesons was measured by placing lead in position I. This is not objectionable, as it is known that penetrating non-ionizing cosmic rays form a negligible portion of the total intensity[3]. The results obtained after taking every possible care to test the counters, circuits, etc., at the end of each measurement are shown in the accompanying table and graphically in Fig. 2.

There is an abrupt drop in the total intensity between the points *A* and *B* on the graph, that is, when the total amount of lead increases from 21·05 to 23·7 cm. This drop is outside the limits of statistical error of the measurements. The slope of the curve before and after the abrupt drop is the same. The drop in intensity, therefore, appears to be real and

Lead in position II = 1·25 cm. Lead in position III = 4·0 cm.

Lead in position I	Counts	Time in hours	Counts/hour
—	7680	81	94·8 ± 0·72
5·2 cm.	4826	52	92·8 ± 0·89
9·3 „	6905	76	90·8 ± 0·73
13·7 „	5430	61	89·0 ± 0·81
15·8 „	3175	36	88·2 ± 1·05
18·45 „	4030	48	84·0 ± 0·89
21·45 „	2581	31	83·3 ± 1·10
24·45 „	3948	48	81·5 ± 0·88

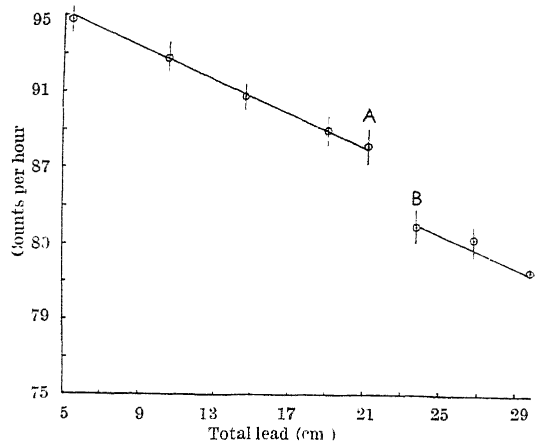

Fig. 2.

not spurious. It occurs when the thickness of lead above the counters 4, 2 and 5 lies between 17·05 cm. and 19·7 cm. This is the region in which the well-known Rossi second maximum has been observed by those who get it[4]. Such a drop in the meson absorption curve has not so far been reported by anybody to my knowledge; but its appearance in this experiment is due to the use of the counter arrangement based on Bhabha's method, which is such as to bring out any existing discontinuities. The interpretation of this experiment, together with the results of further experiments now in progress, will be given in a paper with Prof. Bhabha.

I desire to thank Prof. H. J. Bhabha for his interest and encouragement.

Base Electrolytes for Use in Polarographic Determinations

IN the course of recent research on the application of the polarographic method to the routine analysis of magnetic materials of the 'Permalloy' type, we have found several new base electrolytes which offer considerable advantages for quantitative polarography. They are characterized by the very satisfactory shape of the 'waves', in general free from disturbing maxima, which they yield with a number of metal ions.

Our main problem at the commencement of this work was the determination of iron (12–18 per cent) and molybdenum (2–5 per cent) in the presence of more than 70 per cent nickel and some copper, manganese, etc. We have succeeded in devising and applying our methods to give extremely rapid and accurate routine determinations of these elements in particular, so that to date some six thousand individual determinations have already been made, with a considerable saving of time.

The sample is dissolved in a sulphuric acid–nitric

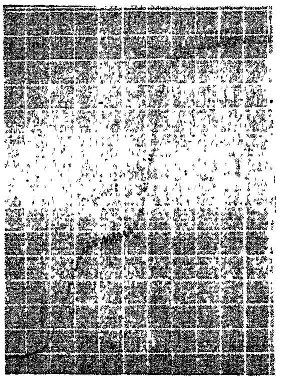

FIG. 1.

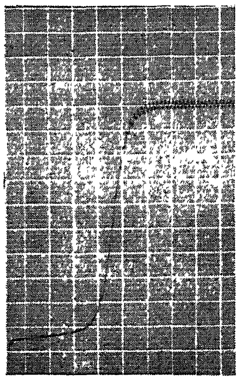

FIG. 2.

acid mixture and made up to a definite volume with distilled water. Aliquots of this mother solution are used in the separate estimations of iron and molybdenum. In the determination of the last-named element, it has been found necessary to remove all traces of nitric acid by heating the aliquot to fumes of sulphur trioxide. After diluting with water and transferring quantitatively to a volumetric flask, the base electrolyte is added and the solution made to volume with water. This base electrolyte is a mixture of citric acid and sulphuric acid chosen so as to give a final concentration in the solution of approximately 0·5 molar and 0·75 *N*. respectively. Under these conditions, molybdenum yields two waves with half-wave potentials $-$ 0·35 volt and $-$ 0·85 volt versus the sulphate electrode (Fig. 1). Since iron and copper are also electro-reduced and interfere with the first wave, we have made use of the second wave. We have observed a deterioration of the wave when the drop time of the capillary in this solution is less than 2·5 sec. at zero applied potential. The *m* value of the hand-drawn capillaries which we use is of the order of 1·6 mgm.sec.$^{-1}$.

In the presence of the other alloying elements in 'Permalloy', we could not determine accurately the iron content by any polarographic method with which we were familiar, but by adding triethanolamine to an aliquot of the mother solution, very useful current/voltage curves were obtained. Some slight advantage was obtained by the addition of ammonia and ammonium chloride, so that the final concentration of the base electrolyte which we employ is triethanolamine 0·3 M; NH_4OH 1·0 M; NH_4Cl 0·85 M. The iron is reduced in two stages in this medium $Fe^{+3} \rightarrow Fe^{+2}$, $E\frac{1}{2}$ $-$ 0·5 volt vs. the S.C.E. (Fig. 2), which is the wave employed in this method, and $Fe^{+2} \rightarrow Fe$, $E\frac{1}{2}$ 1·6 volts vs. the S.C.E. Copper interferes to some extent with the iron wave in this medium, and a rough preliminary separation is necessary in those alloys which contain copper.

These results have led us to study further the ethanolamines as complex-forming agents which can be used, either alone or in conjunction with inorganic salts, as base electrolytes. Some preliminary work has also been started on related organic amines. It appears that these reagents constitute a new and valuable class of base electrolytes.

The properties of the amines can be considerably modified by adding sodium (or ammonium) hydroxide, chloride, sulphate, etc., to achieve separation, suppression or shift of the waves corresponding to various metal ions. It appears as if these electrolytes will be of great use for determining, *inter alia*, iron, copper, nickel, lead, cadmium, barium, cobalt and zinc. Some work has also been started which seems to indicate that aqueous ammonium acetate has a distinct advantage in certain quantitative determinations, notably cobalt, lead, manganese, cadmium, nickel, copper and zinc.

We hope to be able to publish a full account of this work at a later date.

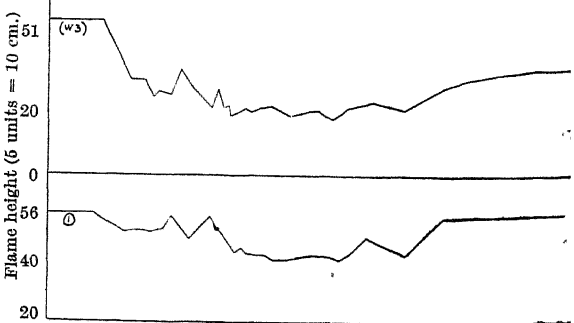
Simple Sensitive Flames

MANY years ago a communication of mine on this subject appeared in NATURE[1]. My interest at the time was only in producing a simple detector of sound waves, but as one of the jets I then prepared was afterwards used by Dr. G. Burniston Brown in his investigation of the properties of sensitive flames in general, and is described by him as the most sensitive he used, I was naturally interested in his conclusion, surprising and difficult to explain, that the sensitive frequencies found expressed a property of the particular gas and not one due to causes inherent in the apparatus used[2]. Later, Brown suggested that the reaction of the surrounding air to the passage of vortices up the jet might be the controlling factor[3].

In the Physical Society's twenty-fifth Guthrie Lecture[4], Prof. E. N. da C. Andrade seems to dismiss Brown's results somewhat lightly and claims that the origin of such selective responses must be sought in resonances of the particular apparatus and room, although Brown himself appears to have obtained the same frequencies in a different laboratory and with different apparatus[2], and Savić to have found that frequencies measured in Basle agreed with Brown's[5].

A critical comparative examination of the two claims would involve a long investigation; but it occurred to me that Andrade's particular contention could be simply tested by repeating experiments similar to Brown's but under entirely different conditions. Accordingly I made a new glass jet by the old process and investigated its response to pure tones of different frequencies given by a calibrated Muirhead beat-tone oscillator. The curve of flame-height against frequency I obtained is reproduced



Upper curve: London, 1931. W3 brass jet (Brown). Lower curve: Manchester, 1942. No. 1 glass jet (Sutherland).

and for comparison I have plotted Brown's curve for the brass jet W3 operated under a different gas pressure in a room quite different in size and character.

By kind permission of Dr. Ewing my experiments were carried out in a very heavily lagged room in the Department of Education for the Deaf in the University of Manchester, and Dr. T. S. Littler kindly assisted in taking the readings. Though this set of observations and Savić's cannot be held to prove Brown's theory, they do suggest that his results were not fortuitous.

Dealkylation of Phenolic Ethers

SEVERAL methods have been reported in the literature for the dealkylation of ethers; for example, with hydrobromic acid[1], hydriodic acid[2], aluminium chloride[3], aluminium bromide[4], alkyl magnesium iodide[5], aldsol[6], piperidine or moist pyridine[7], aniline hydriodide in aniline[8], and magnesium iodide. Some of these methods appear to be of specific nature only.

I have found that although piperidine and moist pyridine failed to demethylate β-methoxynaphthalene at their boiling points, yet partial demethylation occurred when the reaction was carried out in a sealed tube to 250–300°. Aniline hydriodide in aniline, however, did not effect this demethylation even when heated to 250–270°. The use of quinoline hydriodide or aniline hydriodide in boiling quinoline instead of aniline gave satisfactory results. Although other solvents such as dry pyridine, diphenyl-amine, phthalimide and acetanilide, but not dimethylaniline or α-methylnaphthalene, could replace quinoline, yet the extent of demethylation is much less. The following ethers have been similarly demethylated: 4-methoxy-diphenyl, 6-bromo-2-methoxynaphthalene, 4-nitro-2-methoxynaphthalene, 2- and 4-methoxy-1-benzoylnaphthalene. The mechanism of the reaction is under investigation.

Experimental Observations on the Relation between Leaf Development and Stelar Morphology in Species of Dryopteris

THE classical accounts of vascular structure in leptosporangiate ferns show clearly that the interruption of the conducting cylinder of the shoot is associated with the 'insertion' of the leaf-traces, that is, the vascular strands of the petiole or leaf-base. Thus, in a solenostelic fern, a cross-section at the level where a leaf-base joins the shoot will show the presence of a leaf-gap; in other words, the vascular

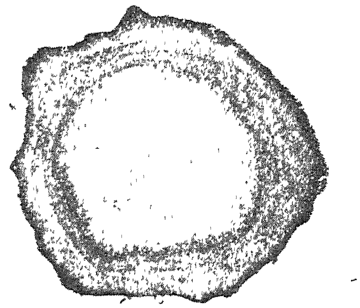

Fig. 1. *Dryopteris aristata*: TRANSVERSE SECTION SHOWING INDUCED SOLENOSTELE IN EXPERIMENTAL REGION OF SHOOT. (× 4.) (PHOTO BY E. ASHBY.)

cylinder which would otherwise be continuous is interrupted by non-vascular tissue, usually parenchyma. In shoots where the leaf-gaps overlap, the vascular system becomes an open meshwork, or dictyostele, each individual strand being described as a meristele. Various tentative physiological explanations have been advanced to account for the development of these leaf-gaps. A considerable volume of literature also deals with the question as to what extent the vascular tissue of the shoot is of truly cauline origin, or alternatively, is a composite structure largely composed of decurrent leaf-traces. So far as I am aware, these problems have not been approached by direct experimental methods. The simple and easily repeatable technique, described below, has resulted in experimental observations of very considerable interest.

The distal ends of erect shoots of *Dryopteris aristata* and *D. filix-mas* were completely defoliated and the scales removed so that the terminal region was left 'naked'. The apical meristematic cone was left intact, but the minute leaf primordia round its base were destroyed by needle-puncturing. For this purpose a Zeiss micromanipulator was used, the material being observed under a binocular microscope. Alternatively, by using a needle on its side and gently moving it over the surface of the shoot away from the base of the apical cone, it was possible to 'smooth

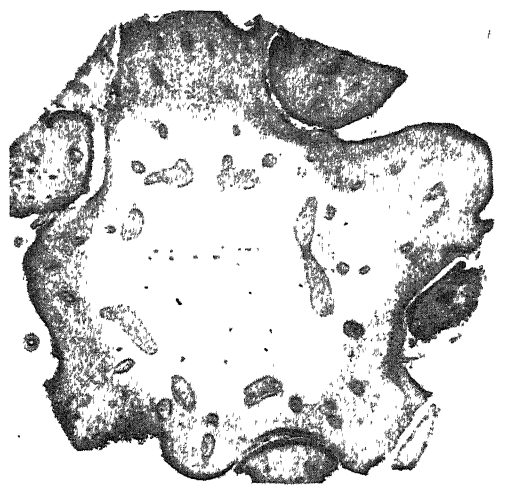

Fig. 2. TYPICAL DICTYOSTELE AND LEAF BASES IN THE UNTREATED REGION BELOW. (× 4.) (PHOTO BY E. ASHBY.)

out' all new leaf primordia without injury to the apical meristem. The apical region was then protected by means of moist cotton-wool and the piece of shoot placed in peat. New leaf primordia were similarly destroyed at weekly or fortnightly intervals. New roots were abundantly formed and some pieces of material were kept alive and in a state of growth for several months, until, in fact, the material was fixed for sectioning.

Transverse serial sections from the apex downwards showed the apical meristem to be still intact and apparently normal, and every stage between complete solenostely and the normal dictyostelic condition of the older region of the shoot was observed (Figs. 1 and 2). Thus where a succession of leaf primordia had been destroyed immediately after their inception, a complete, uninterrupted vascular ring was to be observed; but where a primordium was rather older before it was destroyed, leaf-gaps of small size were present.

A full account of these observations will be given elsewhere.

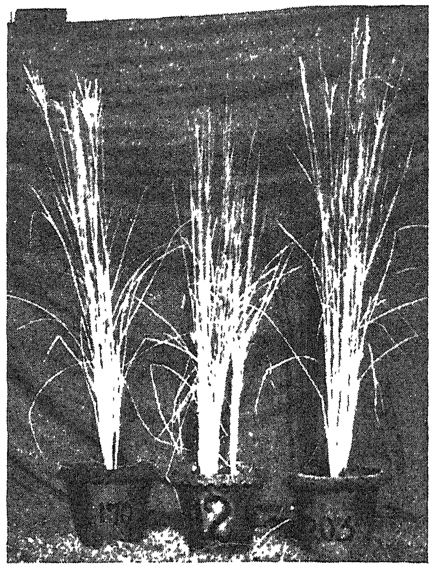
Vernalization of Rice by Short Days

VERNALIZATION by light or the treatment of seedlings to exposures of different light periods in order to accelerate flowering has been effected in temperate cereals. Cailahjan[1] vernalized several varieties of winter wheat and winter rye by continuous light when low temperature had no effect on flowering. Purvis and Gregory[2] have shown vernalization of winter rye both by low temperature and by short days of ten hours. These results indicate the use of light periods for vernalizing cereals which do not respond to Lysenko's method of low-temperature treatment.

Experiments performed by me have shown that vernalization of rice by chilling (3°–6° C.) produces no significant earliness, while treatment of young seedlings by exposures to short days accelerates ear-emergence and increases growth-rate and grain-yield. Seven days old seedlings of a winter variety, 'Bhasamanik', were exposed to eight and ten hours of daylight for varying periods up to six weeks in the seed bed, then the seedlings were transplanted in pots and grown in the field under natural long days. In another experiment short days were given to seedlings in seed bed and continued after transplantation until the ear-emergence was noted in the individual plants. The control plants were exposed all through to normal daylight. Of the seed bed treatments for varying periods an exposure to short days for six weeks duration induces the maximum earliness and grain yield. The results are presented in the accompanying table and the ear-emergence in the treated plants is illustrated in the photograph.

Treatment		Earliness in days (Mean of 15 plants)	Percentage increase of grain yield over the controls (Mean of 15 plants)
	Short days in hours		
Seed bed for 6 weeks	8	10·3	16
	10	12·5	10
Prolonged until ear emergence	8	25	35·3
	10	26·5	18·3



Although greater earliness and yield is obtained by the prolonged treatments, the application of the method in field practices is possible only by the treatment of seedlings in the seed bed. This method of inducing earliness and increased yield is of agricultural importance for the variety of rice grown after transplantation.

A detailed report of the work will be published elsewhere.

I desire to thank Prof. S. P. Agharkar for the facilities to carry out this investigation.

Excretions, Ecology and Evolution

PROF. E. J. SALISBURY's important remarks on the probable significance of excretions in biological competition[1] should not need emphasis, although the work of Pickering[2] in 1917 provides yet another reference regarding the excretions of roots. It is to be hoped that the present interest in penicillin may attract the attention of biologists to what appears in reality to be another aspect of that great field of biological study which embraces chemical morphogenesis, endocrinology and, as is now emphasized, ecological and evolutionary succession. In each of these the production of metabolites plays a part in the mediation of subsequent events.

While working under Prof. A. C. Hardy at the time when he was developing his theory of 'animal exclusion'[3], I became interested in such relationships in the sea. Having in mind the striking collection of references collected by Allee[4,5], I was later led to suggest[6] that these 'exclusive' processes might not only be comparable with others in which the excretions of one form were found to be harmful in some instances, but also with those in which the effects of excretions appear to be beneficial at least to some section of the community. The suggestion was made that such processes may, through the continued

biological conditioning of the environment, play a part in the phenomenon of succession in the sea and elsewhere. If this is correct, then it seems likely that Prof. Salisbury's suggestion regarding biological competition may fairly be seen within the wider field of general ecological succession. In particular relation to penicillin, it would be of interest to know whether its effects on the ecological successors of *Penicillium notatum* are harmful or beneficial, since it is possible that at least one of these has acquired tolerance of the excretion, or even 'made use' of it in an adaptive manner.

As a further example of the possible importance of such processes, I should like to refer again[6] to the part which biological conditioning of both types may have played in that major 'succession', evolution itself. It has been pointed out by P. G. 'Espinasse[7] that physiologically active substances are frequently metabolites in which the present-day effects have followed upon their first production. Much of the history of evolution has concerned the development by living things of responses to metabolites, sometimes their own and sometimes produced by others. Those organisms which developed 'satisfactory' responses succeeded, and those which did not, failed. Particularly in so far as evolution may first have proceeded in an aquatic environment, the gradual production of different external metabolites must at each stage have determined to some extent which of new genetic forms should 'succeed' in the field.

Since this letter was written, H. McIlwain's important article has been published[8], and attention should be directed here to his most relevant remarks on biological interactions.

p-Aminobenzoic Acid and its Effect on the Sulphanilamide Inhibition of the Growth of Oat Roots

THERE have been many observations on the inhibitory effect of sulphanilamide on the growth of various organisms such as bacteria, yeast, fungi and higher plants. In a recent letter by Brian[1], it was shown that sulphanilamide caused an inhibition of the coleoptile growth of wheat seedlings. The general observation was also made that root-growth was stunted. Brian's results seemed to indicate that the antisulphanilamide activity of *p*-aminobenzoic acid could be absolute, indicating that *p*-aminobenzoic acid was an essential metabolite for wheat seedlings.

In view of these findings, it might be of interest to others in this field to record some observations made in these laboratories on the growth of oats, during the course of some work on *H* 11 extract. It was desirable at one stage to maintain a stock solution free from bacterial growth, and attention naturally turned to sulphanilamide and to the range of concentrations which would be non-toxic to the plants. The seeds (var. Victory, *ON* 160) were germinated and grown for 48 hours in the dark at 25° C. using the technique previously described[2].

TABLE 1. GROWTH OF ROOTS IN TEST SOLUTIONS AS A PERCENTAGE OF THE GROWTH IN WATER.

Test substance	Molar concentration 0·00005	0 0001	0 00025	0 0005	0·001
Sulphanilamide ..	101 1	97 4	85 8	74·8	45·1
p-Aminobenzoic acid ..	96·8	96 0	97·3	93 2	91·0

TABLE 2 GROWTH OF ROOTS IN TEST SOLUTIONS AS A PERCENTAGE OF THE GROWTH IN WATER.

Concentration of sulphanilamide	Concentration of *p*-aminobenzoic acid nil	0·000005 *M*	0·00005 *M*	0·0001 *M*	0 00025 *M*	0·0005 *M*	0·001 *M*
0 001 *M*	46·0	42 1	50·0	50 5	57 0	55·3	53 0

From Table 1 it is seen that the inhibition of growth by sulphanilamide alone first began to be observable at a concentration of approximately 0·0002 *M*, while in a concentration of 0·001 *M* the growth of the roots was approximately 45 per cent of that in tap water. With *p*-aminobenzoic acid alone, the roots showed no stimulatory effects, and indeed some slight degree of inhibition appeared at 0·001 *M*. Using *p*-aminobenzoic acid in relatively non-toxic concentrations, it was not possible to neutralize completely the inhibitory effect of sulphanilamide (Table 2). Some degree of anti-sulphanilamide effect could be obtained, the growth-value increasing from about 45 per cent to a maximum of 57 per cent, a difference representing that between the inhibition caused by a 0·001 *M* and a 0·0008 *M* solution of sulphanilamide. That is to say, a concentration equivalent to about 0·0002 *M* sulphanilamide had been 'neutralized' in its effect by *p*-amino-benzoic acid. With a weaker concentration of sulphanilamide (0·0005 *M* or less) there can be an absolute anti-sulphanilamide effect by the *p*-amino-benzoic acid.

There is thus a 'residual' inhibitory effect not affected by the concomitant application of *p*-amino-benzoic acid when the sulphanilamide is present as a 0·001 *M* solution. These results have been confirmed several times, and we must conclude that the 'residual' inhibition noted above represents an effect of sulphanilamide other than the usually accepted one. Sulphanilamide may indeed be able to 'lock' more than one system of reactions, as, for example, the anti-catalase effect noted by Shinn, Main and Mellon[3], and the inhibition of the oxidation of *p*-aminobenzoic acid catalysed by peroxidase[4].

From the present findings it would appear that *p*-aminobenzoic acid is not, in the fullest sense of the term, an 'essential' metabolite for the growth of oat roots (var. Victory) when these are grown for 48 hours in the dark at 25° C. It does, however, play some part in the physiology of the seedling growth and is, no doubt, present in the seed. It may well be that some other analogue of sulphanilamide could be shown to be such an 'essential' metabolite, a point of interest to workers on the growth of isolated roots of monocotyledons.

I wish to express my thanks to Mr. L. G. Wilkinson for his assistance in this work.

Fat of Sow's Milk

Ellis and Zeller[1] studied the changes in composition of the body-fat of hogs at successive intervals of growth and reared on a ration low in fat. A steady decrease in linoleic acid content occurred from a maximum in suckling pigs up to a weight of 170 lb. They concluded from the low iodine value of sow's milk fat (51·6) that sow's milk was not the source of the relatively high proportion of linoleic acid in the small animals. Callow[2] showed that the iodine value of pig back-fat increased with age until weaning, and regarded this increase as due to assimilation of unsaturated acids from sow's milk. Milk from a slaughtered sow, milk from an unspecified source, and colostrum were shown[3] to have fats with iodine values 80·9, 53·6 and 101·8 respectively. In a subsequent discussion[4] of the relationship between age, rate of growth, and iodine value of pig fat, Callow considered that pre-weaning and post-weaning growth differed in some way not understood.

A sample of sow's milk (130 ml. containing 7·0 per cent fat) obtained by hand-milking a Berkshire sow at appropriate intervals over the period of a week has been examined in this laboratory.

COMPONENT FATTY ACIDS (MOLS PER CENT)

	Steam-volatile	Myristic	Palmitic	Stearic	Hexadecenoic	Oleic	Octadecadienoic	C_{20-22}
Sow's milk fat (Laxa[5])	1·5	2·7	28 0	—	—	67·8	—	—
Sow's milk fat (this investigation)	2·4	1·8	28·3	6·1	8·8	35·0	14·0	3·6
Pig outer back fat (this investigation)	—	1·0	28·8	11·5	5·8	46·0	5·7	1·2

The results of this investigation confirm the presence of not more than small amounts of steam-volatile fatty acids, as found by Laxa[5], whose method did not involve ester-fractionation and gave no indication of the proportion of unsaturated components other than oleic acid. The palmitic acid content is within the range of 28–30 mols per cent typical of animal depots, as found by other workers for buffalo and camel milk fat, but not for sheep, goat, or cow milk fat[6]. The hexadecenoic acid content, and the content of polyethenoid C_{20-22} acids, are both rather greater than found for cow and other animal milk fats[6].

As in the case of cow-milk fats[7], only traces of ether-soluble, petrol-insoluble bromides were obtained by bromination of unsaturated C_{18} fractions. It is unlikely, therefore, that the large amount of polyethenoid C_{18} acids present in these fractions was assimilated by the sow from dietary maize meal and barley meal, the polyethenoid C_{18} acid from which consists largely of linoleic acid. The high unsaturation of the C_{18} fractions from this sample of sow's milk fat may have originated from pasture lipids which are known to contain an octadecadienoic acid isomeric with linoleic acid[8]. Linolenic acid, however, which is a major component acid of pasture lipids, was not detected in this sample of sow's milk fat. It is interesting to note that the milk of pasture-fed cows contains only small proportions (2–4 per cent) of octadecadienoic acid, and the addition of oils containing linoleic and linolenic acids to cow's diets produces no significant increase in the amount of polyethenoid acids in milk fats[9,10].

As compared with butterfat, therefore, it seems probable that sow's milk fat contains more octadecadienoic acid, and the assimilation of this acid from the diet of the suckling pigs provides a reasonable explanation of the increase in iodine value of pig depot fat from birth until weaning.

A Standardized Antibacterial Pyrogen-free Metabolite Preparation containing Living *Penicillium notatum*

A SUSPENSION of *Penicillium notatum* (Fleming) hyphæ in a fluid medium, obtained from below the mycelium of the mould at the stage of its highest rate of penicillin production and freed from pyrogens and other impurities, contains also antibacterial metabolites which are normally present in penicillium culture fluid. From its therapeutic results on animals, it appears that the effects of this suspension, in addition to the penicillin effect, are due to the presence or production of other potent bacteriostatic compounds—which are destroyed or left behind in the manufacture of penicillin—and to the continuation of the formation of penicillin *in vivo*.

From observations on animals it has been found that the suspension is active in the presence of serum, pus, blood and tissue autolysates, and is not inactivated by sulphonamides or sulphonamide inhibitors. It has, so far, not proved pyrogenic in animals or man, and has shown no signs of local or general toxicity, allergic sensitization or discomfort except for a slight local burning sensation after injecting, lasting only a few minutes. It appears to differ, therefore, from crude penicillin extracts containing no living cultures, which can cause toxic and sometimes painful reactions due to impurities present. Whereas a single dose of several thousand Oxford units of penicillin is rapidly eliminated in the urine, the therapeutic effect of one injection of the suspension (1 c.c. per 20 lb. bodyweight), on the other hand, appears to last for 36–48 hours. Where the response to one intramuscular injection did not completely clear an infection, a second injection in most cases did so. The characteristic fall of fever in pyrogenic infections within three to four hours of administering a dose of the suspension, and the immediate relief of pain observed in a number of infections in the experimental animals, are clear and typical indications of the promptness of the therapeutic response to the preparation.

Twenty-one cases of animal infections were treated with the suspension. Of these, fourteen were absolutely positive—three of them astonishingly rapid in response—three were doubtful and inconclusive, and four were negative. No ill-effects were observed in any of these cases. In the four negative cases

no harmful effects could be attributed to the injection, even when given intravenously. The infections which responded to treatment were gastro-intestinal (*B. coli*), staphylococcal, streptococcal and pneumococcal types, while virus infections do not seem to respond.

This preparation from *Penicillium notatum* seemed exceptionally potent in the treatment of open wounds with pyrogenic mixed infections, and also when used intramuscularly for the treatment of pyrogenic and gastro-intestinal infections. The evidence of its value in old chronic infections is inconclusive. It appears that intramuscular injections are as efficient as intravenous injections. The preparation is standardized for the hyphæ content by the turbidity against barium sulphate (nephelometer) or by an indirect all-count in comparison with a drop of blood. The antibacterial activity can be assayed *in vitro* by the Florey-cup or by the Fleming dilution method, or *in vivo* by animal protection tests.

In human beings the preparation is well tolerated without toxic reactions or sensitization becoming apparent. The therapeutic response is prompt, usually within 3–4 hours after the first injection. Controlled clinical results have already been obtained in sulphonamide-resistant pneumonia, acute staphylococcal, streptococcal and other infections, and it is hoped they will be published shortly.

We wish to express our thanks to Mr. E. von Lustig-Lendva, who was responsible for carrying out the preliminary animal tests.

Origin of Indo-European Languages

COMMENTING on Prof. Alexander Jóhannesson's recent article, Mr. Allan S. C. Ross[1] states: "In all languages known to us . . . for the great majority of words, the connexion between sound and sense is random". But he does not say whether this also applies to the connexion between mouth gesture and sense, which was what Prof. Jóhannesson has been particularly investigating.

Yet it can scarcely be disputed that the sounds of speech are, in fact, a secondary effect of the gestures of articulation which produce the various sounds of speech. If this is so, then it would appear that the "excellent minute" of the Société de Linguistique which Mr. Ross quotes is out of date, and that the "origin of language" is now ripe for discussion, on the basis of mouth gesture.

Having made a fairly wide examination of the connexion between mouth gesture and sense in various languages, and of the meaning which hand gestures (in sign language) and mouth gestures (in speech) actually convey, I can offer evidence of the survival of significant mouth gestures. In English, for example, about 75 per cent of all the short words are 'gestural'; that is, the mouth gestures which produce the words are themselves a pantomimic representation of the primitive meaning of the words. Thus, of the 79 short words beginning with *GR*- (a gripping, surrounding, enclosing or clawing gesture), 73 per cent are gestural; of the 25 short words beginning with *SCR*-, *SKR*-, 88 per cent are gestural, and of the 39 short words beginning with *STR*-, 90 per cent are gestural, while 100 per cent of short words ending in -*OOP* or -*OUP* are gestural.

In Chinese the same conditions obtain; and of 36 words pronounced *KU* or its variants (*K'U*, χU, χUA, *KÜ* and *KUAI*) 34 (94 per cent) are found to be gestural. Similarly, of 19 short Greek words beginning with γλ- (*GL*), 15 (78·9 per cent) are gestural. Such connexions can certainly not be described as random.

Mr. Ross also states that "linguistic changes which must have operated in the long period intervening" (that is, between the origination of a language and its development as a written language) "would certainly have quickly reduced a non-random sound-sense relation to a random one". On this count also the gestural evidence is against him.

Investigation of the mouth gestures involved in "linguistic changes" and "ablaut" shows that, as a rule, the original significant gestures do not change; what changes is the manner in which the individual gestures are made, the changes being mostly in the direction of unconsciously making the gesture easier to perform. Thus, a complete closure of the tongue against the throat, palate or back of the teeth may become a partial closure *in the same position*. A complete lip closure may become a partial closure, a voiced consonant may become unvoiced, or the level of the tongue or the opening of the lips may be varied, for convenience in combining a given vowel posture with a particular consonant gesture. In other words, the 'fashions' in performing the mouth gestures vary—like other human fashions—but the gestures persist. Philologists should study mouth gestures. If they fail to do so, they will be in no position to criticize Prof. Jóhannesson's theories.

Human speech is, admittedly, a highly important branch of human behaviour; if its votaries will study the system of gestures to which audible speech is due, philology will indeed become a science, and—linked with the study of sign language—will take its place as an essential part of anthropology.

Pectoral Gland in Apes and Monkeys

PROF. OSMAN HILL's interesting account of the gland on the chest of a male drill[1] reminds me that nearly twenty years ago[2] I described and figured a somewhat similarly situated gland in two adult male gibbons from Borneo. In these apes, the glandular area superficially is an elongated triangular patch of thickened skin sparsely covered with short hairs, and in one of the specimens with blackish secretion. It is broad above and narrowed below, and extends from the region of the inner ends of the collar-bones downwards and terminates in a point a little below the mammæ. Although I had one of these gibbons under observation in the Zoological Gardens at Regent's Park, London, neither I nor the keeper in charge ever saw the animal evince the least sign of being aware of the existence of the gland; but Prof. Hill's amusing description of the conduct of the drill in connexion with its pectoral gland shows that there is still a great deal of interesting information about the behaviour of wild animals to be learnt by observing them in captivity.

ELECTRICITY SUPPLY IN GREAT BRITAIN

TWO documents have recently been published on this subject which are likely to have important repercussions in the electricity supply industry of Great Britain. The first of these is a memorandum issued by the Incorporated Association of Electric Power Companies*, and the second is the report made to the Council of the Institution of Electrical Engineers by its Post-War Planning Committee, on electricity supply, distribution and installation†.

Administrative Aspects

The memorandum issued by the Incorporated Association of Electric Power Companies refers to the progress of, and developments and legislation in, the supply industry, to the Electricity Commission, and to the work and recommendations of the McGowan, Cooper, and Scott Committees. Proposals are then made for the consideration of the Minister of Fuel and Power in respect of (1) electricity distribution, and (2) the Electricity Commission. Their essential features are abstracted in the following.

Electricity Distribution. Improvement should be generally on the lines of the McGowan Report, subject to the amendments cited later. Legislation should be passed at or before the end of the War to suspend the exercise of the rights of purchase by local authorities and others of any electricity undertaking, but such suspension should not prevent the completion of negotiations for the voluntary acquisition or amalgamation of such undertakings. The Electricity Commissioners should delimit suitable electricity districts and appoint a scheme committee for each district to prepare and submit to the Commissioners a draft scheme for the improvement of distribution in the district in accordance with the terms of the McGowan Report. The scheme committee should consist of representatives of the authorized undertakers in each electricity district. Should the scheme committee fail to prepare or forward a draft scheme for any electricity district, the onus would fall on the Electricity Commissioners.

The Electricity Commissioners should be empowered to make any scheme, but should not make one other than an agreed scheme without holding a local inquiry. The Minister of Fuel and Power should be empowered to confirm any scheme made by the Electricity Commissioners, and any scheme confirmed should be subject to the approval of Parliament. The proposed legislation should prescribe the basis of the purchase price to be paid for the acquisition of any undertaking. Tariff forms throughout Great Britain should be standardized so far as possible. Complete uniformity of charges for the whole country is not economically possible, but may be feasible in an electricity district, and has already been attained in a number of large areas. Retained undertakers should be under an obligation to standardize voltages and systems, as may be determined by the Electricity Commissioners. Legislation should provide in the case of retained undertakers for the application of an effective sliding scale relating prices to costs and charges, including a reasonable return on capital employed. All retained undertakers should be obliged to submit periodically to the Electricity Commissioners proposals for the development of the supply of electricity for general domestic purposes, including lighting in any part of their area where there is a demand for such a supply and a prospect of such supply affording reasonable return to the undertakers.

The Electricity Commissioners should appoint a local committee in each area to consult with the retained undertakers on matters affecting development of supplies and prices. The local committee should be representative of local authorities and consumers and should have power to initiate applications to the Electricity Commissioners regarding such matters.

The present system of valuation and rating as affecting the industry has been adversely commented upon by various departmental committees, and it is considered that the whole system should be reviewed. The proposed legislation should include various provisions recommended by the McGowan Committee on matters such as the procedure for obtaining wayleaves, fixing wayleave rentals and compensation, public supplies of electricity by unauthorized undertakers, and the consolidation of the numerous Electricity Acts into one up-to-date enactment. It is considered that the conclusions of the McGowan Committee and the Cooper Committee and also the views already expressed regarding public corporations and regional boards apply equally to 'public ownership'. If, however, Parliament decides that retained company undertakings should be liable to purchase by some form of public authority, it is considered that the prescribed period should be not less than fifty years and that the option to purchase should be exercisable at the same date for all undertakings. If, at the expiry of fifty years, purchase were not deemed expedient, there should be recurring options at reasonably lengthy intervals.

The Electricity Commission. It is the view of the Incorporated Association of Electric Power Companies that the establishment of the Electricity Commission was and is still necessary to the industry. The Minister should have the widest choice in appointing suitable men to the Commission, and the Commissioners, in turn, should be enabled to appoint an experienced and well-paid staff. It is recommended that five Commissioners be appointed at the earliest possible date and that all the Commissioners, including the chairman, should be men of long and wide experience in the industry. The staff of the Commission should be strengthened and reorganized at the earliest possible date and there should be removed any obligation that its members should be governed by Civil Service conditions and rates of pay. The Electricity Commissioners should have the assistance of an advisory committee to be appointed by the Minister of Fuel and Power after consultation with the electricity supply associations, in regard to the delimitation of electricity districts and other proposals.

Technical Aspects

The second report, sponsored by the Institution of Electrical Engineers, is confined to technical matters of immediate urgency in connexion with electricity supply, distribution and installation in Great Britain, and it excludes problems of generation and main

* Memorandum with regard to the Electricity Supply Industry in Great Britain. Pp. 30. (Incorporated Association of Electric Power Companies, 58 Abbey House, Victoria Street, London, S.W.1. 1943.)

† Electricity Supply, Distribution and Installation: a Report to the Council of the Institution of Electrical Engineers from the Post-war Planning Committee. Pp. ii+26. (Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2. 1944.)

transmission, for which technical policy is already co-ordinated by the Central Electricity Board.

For low-voltage distribution systems, a four-wire, three-phase, 400/230 volt system is the national standard. Its extension throughout Great Britain is recommended as an urgent post-war national industrial plan. Data are given on which a scheme to secure standardization may be based. Complete standardization of all low-voltage distribution systems presents no technical difficulties and could be completed within five years. As the benefit of such voltage standardization mainly accrues to the entire community, it may be the subject of financial discussions with Government, and a detailed estimate has been made of its cost, which amounts to some £17·5 millions, based on 1939 conditions and price-levels.

A brief historical review of the development of urban electricity in Great Britain leads up to the position in 1939, when of 10·7 million urban dwellings, 7·9 million were supplied with electricity; among 2·25 million rural dwellings, 1·1 million received a supply, together with at least 35,000 farms. For the completion of rural electrification financial aid will be required for connecting consumers remote from transmission lines, preferably granted for schemes embracing districts as a whole. Wayleave procedure should be simplified and the use of under-eave construction facilitated. Agreement by undertakings on a standard length of underground service cable, laid free, is recommended. A free overhead service line to a total cost not exceeding that of installing the agreed length of underground service cable is suggested. Simplified and less expensive constructions for high-voltage spur lines are proposed, and agreed standards are recommended. Expenditure on such overhead lines must usually be justified by adequate revenue, unless the consumer contributes to first cost or a subsidy is available. Legislation is recommended to bring English law into conformity with Scottish law, which allows a tenant to secure compensation from the landlord for the cost of any wiring installation put in by the tenant. Low-interest loans for wiring, etc., or hire-purchase terms for a ten-year period are advocated.

A report issued in 1930 of a committee set up by the Electricity Commissioners gave a comprehensive picture of the situation at that time and remains largely applicable. The time is appropriate for securing uniformity of tariff forms, and recommendations are made to this end. The merits of the two-part tariff are discussed and recommendations for its wide extension are made. Consumers are classified into the groups domestic, farm, industrial and commercial, and recommendations are made for the equitable assessment of the fixed or primary charge component of the tariffs appropriate to each group. The Electricity Commissioners, it is suggested, should be authorized to permit any undertaking to offer a two-part tariff only, with no alternative flat-rate, subject to certain safeguards to the consumer. Descriptions are given, and the advantages are discussed, of two-part variable-block tariffs, for the above groups, and examples of the working of each are quoted.

Basic changes in the Regulations for the Electrical Equipment of Buildings of the Institution are proposed, leading to their division into Basic Safety Regulations (accompanied by a Code of Practical Interpretation) and supported by Codes of Good Practice to be prepared by the independent Codes of Practice Committee, set up under the ægis of the Ministry of Works. It is recommended that this very important matter be given early consideration.

No full assessment of the matter of legislative control of the electrical equipment of buildings has been attempted, but an appraisement of the technical aspects of the available evidence does not support a need for the compulsory registration of contractors and operatives or for the exactment at present of compulsory wiring regulations. If necessary, the proposed Basic Safety Regulations could later be given the force of law. Extension of inspection of installations by supply undertakings, more general observance of the wiring regulations, wider use of the voluntary system of registration of installation contractors, insistence on the use of non-kinkable cords for portable apparatus, and the manufacture of accessories and apparatus to extended and specific British standard specifications are recommended.

OPHTHALMOLOGY IN GREAT BRITAIN

THE work of the modern ophthalmologist and the tasks he has to face in the future are the subjects of two articles in the *British Medical Bulletin* (1, No. 9; 19 3). These articles inaugurate a series of outlines of special aspects of British medicine which that journal will publish at irregular intervals in the future.

Discussing the future work of the ophthalmologist, Prof. Arnold Sorsby gives most of his space to blindness, adopting the criterion that blindness means being "so blind as to be unable to perform any work for which eyesight is essential". He finds that there are at least 100,000 blind people among the population of about 40 million in England and Wales, which is a rate of 2·5 per thousand. It is likely that even now all the blind are not registered by a medical examiner for the benefits obtainable under the Blind Persons Act of 1920.

In 1910 it was estimated from the census returns of various countries that there were about 3 million totally blind people in the world, but, on the basis of the rate for England and Wales, the world figure would be 5 million. Blindness is, however, much more frequent in India, China and the Middle East than it is in Britain. China alone probably has 4–5 million blind people and India may have almost as many. Prof. Sorsby suggests that there are probably 15 million blind people in the world, and that many millions more have grossly defective sight. Apart from the immediate exciting causes of blindness, the great determining causes are ignorance and poor social and medical services.

The prevention of blindness—surely one of the major tasks of the future—is considered under five headings. Among the infective processes causing blindness, ophthalmia neonatorum of the newborn is no longer significant, nor is smallpox now a serious cause of eye disease. Trachoma and the acute ophthalmias of the tropics are not yet controlled. Trachoma probably affects about 15 per cent of the world's population, and its cause is not understood. Possibly a remedy may be found among the sulphonamides. The control of tuberculosis has helped greatly to diminish phlyctenular ophthalmia, the prevalent ophthalmia of childhood, due to tuberculous sensitization. Advances in public health and hygiene have

also helped the tasks of the ophthalmologist. But the lack of any specific treatment for tuberculosis makes it difficult to control tuberculous allergy of the eye. Until we find an antisyphilitic agent which will reach and act on the brain and the eye, treatment of ocular syphilis will be unsatisfactory.

Among genetic affections of the eye, malformations and hereditary anomalies cause the blindness of some 50 per cent of blind children. Geneticists should find interesting material in the study of *glioma retinæ*, a disease which behaves as an irregular dominant in some families. We need to know why it does not behave as a dominant in those transmitters of it who do not suffer from it.

Among nutritional and metabolic disorders, xerophthalmia is a major problem in China and India. Work is needed on the correlation of nutrition with ocular health and we need better methods of studying the physiology of the eye, so that problems which, like diabetic retinitis, are related to faulty metabolism of the body as a whole, may be tackled on a proper basis. Such methods would also help the study of cataract and glaucoma, which are, according to English and North American statistics, responsible for 25–40 per cent of blindness.

Finally, in children and young adults, injuries are important. War is the greatest single cause of blindness, and it poses its own special problems—the extraction, for example, of non-magnetic fragments from the interior of the eye, such fragments being, in the present War, largely non-magnetic, while those encountered during the War of 1914–18 were not.

In a section on ocular hygiene Prof. Sorsby echoes the opinions of the leaders of modern medical thought when he reminds us that nowadays we tend to take 'optical aids' as a matter of course, and to forget the environmental conditions of those who have to use them. It is good to learn that England may have a national eye service for all, an important part of which will be the research facilities which are essential to its progress. The *British Medical Bulletin* points out that the Oxford University Ophthalmic Research Endowment Committee is appealing for funds for the endowment of the newly established Department of Ophthalmology at Oxford after the War. Reference was made to this project in NATURE of September 18, 1943, p. 323.

In another special article in this issue of the *British Medical Bulletin*, R. R. James gives an outline of the history of English ophthalmology since its beginnings in the days of the Roman occupation. After the Romans left, the Anglo-Saxons and Normans did little to improve ophthalmic practice, but in the thirteenth century Roger Bacon and John of Peckham initiated the use by old people of lenses for reading, and the science of optics began. Early in the seventeenth century the itinerant oculist Richard Banister of Stamford directed attention to hardness of the eyeball as a cardinal sign of glaucoma, a discovery which was forgotten for 150 years. Banister seems to have been an honest and remarkable member of an itinerant fraternity whose practices should make entertaining reading. Mr. James describes the eighteenth century as the age of ophthalmic quackery, but during it modern ophthalmology was founded by Cheselden, Sharp, Warner and others. In 1805 the Moorfields Eye Hospital, now the Royal London Ophthalmic Hospital, was founded. Exeter established an eye hospital in 1808 and Manchester in 1814. The subsequent landmarks in ophthalmic history given by Mr. James indicate that, when Sir William Bowman, who gave his name to Bowman's membrane, abandoned general surgery to become the first ophthalmic specialist, he began that specialist service which to-day must face so many urgent tasks.

G. LAPAGE.

THIOUREA AS PROTECTIVE AGENT FOR VITAMIN C

FOOD products rich in ascorbic acid, such as those made from citrus and other fruits, should be processed under conditions in which the vitamin is not destroyed. Ascorbic acid loses its antiscorbutic action when the cyclic structure of the molecule is changed by the opening up of the lactone ring. In alkaline solution this takes place spontaneously with formation of diketogulonic acid, which afterwards breaks down to threonic and oxalic acids from which the vitamin cannot be recovered by simple reduction. This does not readily happen in acid solution, and the vitamin may be oxidized to the dehydro form and quantitatively recovered by the use of the appropriate reducing agents.

Oxidation of the vitamin can occur in the absence of molecular oxygen provided the solution is activated by (1) ultra-violet light, (2) copper, (3) pyridine nucleotides, or (4) enzymes of the type of ascorbic acid oxidase. The possible significance of copper contamination has been recognized in an order by the Ministry of Food by which manufacturers of fruit concentrates containing vitamin C are required to satisfy the Ministry that their process plants do not come in contact with fruit juices.

It may be sufficient for industrial purposes to ensure that the boiling pans are not lined with copper, the effect of copper parts of the cold sections of the plant being disregarded. Contamination by ionic copper is likely to be much more troublesome, since the metal may be introduced in the water and carried by the fruit, which is often copper-sprayed. Substances capable of protecting the vitamin from destruction following oxidation are (1) substances which stabilize the vitamin in its oxidized (dehydro) or its reduced forms, since either are of equal value in nutrition; (2) reducing agents capable of maintaining the vitamin in the stable or reduced form; (3) buffers which keep the solvent from becoming alkaline; and (4) substances which act as anti-catalysts either by depressing the ionization of copper present in the solution or by combining with ascorbic oxidases.

Reduced ascorbic acid is stable in tissue fluids and in natural and processed food materials containing appreciable quantities of copper. This stability is due to the presence of substances such as glutathione which form copper compounds of a low degree of ionization. E. Kawereau and W. R. Fearon (*Sci. Proc. Roy. Dublin Soc.*, 23, 171; 1944) have recently investigated a large number of substances which might protect ascorbic acid from oxidation in the presence of copper. Of all the simple solutes tested, thiourea was outstanding in its protective power. It appears to be of very low toxicity and is excreted unchanged by the kidney after administration to human subjects. It displays none of the pharmacological effects possessed by some of the substituted thioureas. The authors, however, consider that more work is required on the effects of long-continued

administration and the possible formation of decomposition products during prolonged boiling with fruit extracts, before the general use of thiourea as a protector of vitamin C in large-scale industrial work can be advocated; but it appears most promising of all compounds tested. Boiled vegetable extracts display a similar power of protection, which in some preparations is so complete as to suggest the presence of specific stabilizers of possibly the thiol class. Cabbage, for example, contained an unidentified volatile thiol compound and potato juice yielded an active distillate on boiling.

EFFECT OF DRINKING SMALL QUANTITIES OF SEA WATER

DR. W. S. S. LADELL, of the National Hospital, Queen Square, London, has studied the effects of drinking small quantities of sea water (*The Lancet*, Oct. 9, 1943, p. 441). The work was done for the Medical Research Council's Committee on the care of shipwrecked personnel (M.R.C. War Memo. No. 8, which does *not* recommend the drinking of sea water). A full report of Dr. Ladell's work will be issued later.

A man requires 800–1,000 c.c. of water a day. With less than this he contracts a water debt to his tissues. With a water debt he continues to produce only 350–450 c.c. of urine a day (instead of the normal 1 litre or so), whether the water debt is large or small. During this low urinary output, the urea concentration in the urine rose to as much as 6 per cent; but the total urea output was inadequate and there was nitrogen retention with a rise of blood urea. At the same time, the salt losses in the urine were high on the first day, but they fell in a day or two to a low level. The diet of each subject of all the experiments was 'shipwreck diet' of 1 oz. daily of biscuits, sweetened condensed milk, butter fat or margarine, and chocolate. This provided not more than 1 gm. of sodium chloride daily, but more than this was excreted, so that, when no sea water or saline was drunk, there was always a slight negative salt balance. There was a definite psychological value in having an extra volume of fluid to drink (water supplemented with 3·5 per cent sodium chloride solution or with sea water), even though it tasted salty.

The results, briefly stated, were that the effects of drinking up to 400 c.c. of sea water a day, when the subjects were either totally or partially deprived of fresh water, were, on the low-calorie and low-salt diet provided, an increase in the output of urine, with an improved total urea clearance; a slight gain to the body of water, because the extra water lost in the urine is less than the extra water taken in as sea water; and an initial retention of chloride equal to the chloride lost before the subjects began to drink sea water and, after this, a full excretion of all the chloride ingested. This restoration of the total sodium chloride content of the body may have been a manifestation of the body's tendency, indicated by the work of others whose work is quoted, to conserve its extracellular, at the expense of its intracellular, fluid.

Readers interested in the medical problems presented by the survivors of shipwrecks will find useful Surgeon-Captain Critchley's book, "Shipwreck Survivors, a Medical Study" (J. and A. Churchill, London, 1943, 7*s*. 6*d*. net).

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Saturday, March 25

ASSOCIATION FOR SCIENTIFIC PHOTOGRAPHY (at the Caxton Hall, Westminster, London, S.W.1), at 2.30 p.m.—"The Assessment of Lens Performance" (Mr. A. Cox: "General Theory of Lens Performance"; Mr. H. W. Martin: "Lens Types and their Characteristics").

BIOCHEMICAL SOCIETY (at the Courtauld Institute of Biochemistry, Middlesex Hospital, London, W 1), at 2.30 p.m.—Annual General Meeting.

Monday, March 27

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C 2), at 1.45 p.m.—Dr. Franklin Kidd: "Dehydration of Foodstuffs" (Cantor Lectures, 2).

Tuesday, March 28

INSTITUTE OF FUEL (joint meeting with the BRITISH COAL UTILIZATION RESEARCH ASSOCIATION) (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 10.30 a.m —Symposium on "Underfeed Stokers as applied to Furnaces".

INSTITUTION OF BRITISH AGRICULTURAL ENGINEERS (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. F. A. Secrett: "Mechanisation in Market Gardening".

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at Lincoln's Inn Fields, London, W.C.2), at 4 p.m.—Prof. Arnold Sorsby: "Blindness in Childhood; Past Achievements and Present Problems".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Sir Henry Dale, G.B.E., Pres.R.S.: "Chemical Factors in Nervous Effects", 2: "The Appearances of Two of these Substances in Nervous Activity; Adrenergic and Cholinergic Nerves".*

INSTITUTION OF ELECTRICAL ENGINEERS (TRANSMISSION SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m. —Discussion on the Supply and Distribution Sections of the Report on "Electricity Supply, Distribution and Installation" prepared by Sub-Committee No. 3 of the Post-War Planning Committee (to be opened by Mr. P. E. Rycroft).

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London, S.W.7), at 6 p.m.—Annual General Meeting. Mr. F. W. Coppin: "Production of Photographic Templates".

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 6.30 p.m.—Mr. J. H. G. Monypenny: "The Sigma Phase and its Significance".

Wednesday, March 29

INSTITUTION OF NAVAL ARCHITECTS (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 12 noon—Annual General Meeting.

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. E. R. Hamilton: "Education To-day and To-morrow", 7: "The Training of the Teacher".

Thursday, March 30

TOWN AND COUNTRY PLANNING ASSOCIATION (at 1 Grosvenor Place, London, S.W.1), at 1.15 p.m.—Rt. Hon. Earl De La Warr: "National Planning Policy in relation to Agriculture".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Mrs. Kathleen Lonsdale: "Diamonds—Natural and Artificial".*

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at Lincoln's Inn Fields, London, W.C.2), at 4 p.m.—Prof. Arnold Sorsby: "The Sulphonamides in Ophthalmology; their Use and Limitations".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. J. A. Harle and Mr. R. W. Wild: "Restriking-Voltage as a Factor in the Performance, Rating and Selection of Circuit-Breakers"; Mr. H. E. Cox and Mr. T. W. Wilcox: "The Influence of Resistance Switching on the Design of High-Voltage Air-Blast Circuit-Breakers".

INSTITUTION OF ELECTRICAL ENGINEERS (CAMBRIDGE AND DISTRICT WIRELESS GROUP) (at the University Engineering Department, Trumpington Street, Cambridge), at 8.15 p.m.—Mr. R. H. Angus: "Transients on Transmission Lines".

Friday, March 31

OIL AND COLOUR CHEMISTS' ASSOCIATION (MANCHESTER SECTION) (at the Engineer's Club, Albert Square, Manchester), at 2 p.m.—Mr. W. A. Silvester: "Patents at Home and Abroad".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Mr. Stanley Unwin: "Publishing in War and Peace".

Saturday, April 1

BRITISH ASSOCIATION OF CHEMISTS (LONDON SECTION) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Prof. R. G. W. Norrish, F.R.S.: "Chemistry and the Community".

Thursday, March 30—Tuesday, April 4

BRITISH PSYCHOLOGICAL SOCIETY (at the Training Centre, Jordanhill, Glasgow, W.3).—Annual General Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned

LABORATORY ASSISTANT (temporary), experienced in pathological and bacteriological work, in the County Public Health Department—The County Medical Officer, County Hall, Wakefield (March 28).

LECTURER IN MATHEMATICS AND CHEMISTRY in the School of Building—The Principal, West Ham Municipal College, Romford Road, Stratford, London, E.15 (March 29)

SENIOR ASSISTANT DRAINAGE AND IRRIGATION ENGINEER (Reference No. E.902A), and a JUNIOR ASSISTANT DRAINAGE AND IRRIGATION ENGINEER (Reference No E.903A), by the Sierra Leone Government—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting the appropriate Reference No) (March 31).

TECHNICAL ASSISTANT, Grade I (location. London, with travelling) (applicants must be qualified electrical engineers with experience of electrically driven excavating machinery)—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.776A) (March 31).

PRINCIPAL OF TOXTETH TECHNICAL INSTITUTE, Liverpool—The Director of Education, Education Offices, 14 Sir Thomas Street, Liverpool 1 (April 1).

TWO FULL-TIME LECTURERS FOR (1) MECHANICAL ENGINEERING and (2) ELECTRICAL ENGINEERING, in the East Ham Technical College—The Secretary for Education, Education Office, Town Hall Annexe, Barking Road, East Ham, London, E.6 (April 1).

WELDING OFFICERS by a Government Department to give technical assistance in designing for welding and the welding of armour plate and fabricated steel structures, etc.—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No C.2060A) (April 3).

EXECUTIVE ENGINEERS by the Gold Coast Government Public Works Department—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.908A) (April 3).

PRODUCTION ENGINEER with mechanical and electrical training and experience, to assist Works Director of large company of manufacturing electrical engineers having several factories in England—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.1973XA) (April 3).

ASSISTANT TO THE DIRECTOR—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (April 5).

METALLURGIST with a sound physical metallurgical or physical-chemical training, for research work connected with Metallic Arc Welding—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.2182XA) (April 6).

READERSHIP IN MINERALOGY—The Registrar, University Registry, Oxford (April 8).

WAYNFLETE PROFESSORSHIP OF METAPHYSICAL PHILOSOPHY—The Registrar, University Registry, Oxford (April 13).

RESEARCH WORKER (who should be a PHYSICIST) in the Coal Treatment Laboratory of the Mining Department—The Secretary, The University, Edmund Street, Birmingham 3 (April 15).

LECTURER (preferably a woman) IN BIOLOGY—The Warden, Goldsmiths' College, at University College, Nottingham (April 15).

ASSISTANT HYDROGRAPHIC SURVEYORS by the Kenya Government Public Works Department—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.904A) (April 15).

PROFESSORSHIP OF ENGINEERING SCIENCE—The Registrar, University Registry, Oxford (April 30).

CHAIR OF PHILOSOPHY at the University of the Witwatersrand, Johannesburg—Dr. William Cullen, 4 Broad Street Place, London, E.C.2 (May 1).

DIRECTOR OF THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

CHAIR OF NATURAL PHILOSOPHY, United College, St. Andrews—The Secretary, The University, St. Andrews (June 15).

BOTANIST (male) in the Branch of Plant Pathology and Botany of the Department of Agriculture, Southern Rhodesia—The Official Secretary, Rhodesia House, 429 Strand, London, W.C.2.

SENIOR LECTURER IN THE PHYSIOLOGY DEPARTMENT—The Secretary, Royal (Dick) Veterinary College, Summerhall, Edinburgh 9.

GRADUATE TEACHER FOR MATHEMATICS with some GENERAL SCIENCE (ordinary National Certificate standard)—The Principal, Technical Institute, Beckenham.

GRADUATE LECTURER IN MECHANICAL ENGINEERING SUBJECTS to Engineering Degree and Higher National Certificate standards—The Principal, Kingston Technical College, Kingston, Surrey.

ASSISTANT MASTER to teach MATHEMATICS, TECHNICAL DRAWING and SCIENCE in the Junior Technical School of the Oldham Municipal Technical College—The Director of Education, Education Offices, Union Street West, Oldham.

TEACHERS (temporary full-time) OF ENGLISH SUBJECTS AND MATHEMATICS; ENGLISH, MATHEMATICS and ELEMENTARY SCIENCE; RADIO and PHYSICS—The Secretary, Northern Polytechnic, Holloway Road, London, N.7.

ASSISTANT (male or female) IN THE CHEMICAL DIVISION of the County Laboratory—The County Analyst, County Buildings, Worcester.

ROYAL COMMISSION ON POPULATION

IN 1937 many members of the present Government voted against the Population (Statistics) Bill. Now, after the lapse of only seven years, the Government has appointed a Royal Commission to inquire into the problem of Britain's population (see NATURE, March 11, p. 310). Before the War this vital issue did not receive the attention it undoubtedly deserved ; in general, the country was indifferent, an attitude which was reflected in Parliament when a considerable section of the House of Commons resisted a measure designed to ascertain certain facts essential to any scientific study of the demographic position of Great Britain. It was alleged that the Bill would lead to some infringement of the personal liberties of the subject. Nevertheless, the operation of the Act during the past six years has not, so far as is known, been attended by consequences of this kind, nor has it resulted in any opposition from the general public. Unfortunately, however, the scope of the Act was restricted on account of the reception given it by the House of Commons and by certain sections of the Press, with the result that the facts at our disposal to-day are less comprehensive than they might have been.

It is indeed satisfactory that, despite the debates of 1937 and the subsequent issue in 1942 of a reassuring White Paper on the future trend of population, the Government has changed its mind and has appointed a strong Royal Commission. It will be the task of future historians to identify and assess the influences which led, in the fourth year of war, to this decision. It cannot be due to the trend in the birth-rate since 1937, for it has risen from 14·9 to more than 16·0 per 1,000 population.

The Commission, under the chairmanship of Lord Simon, with its three attendant technical Committees (Statistical, Economic, and Biological and Medical) numbers among its personnel many authorities on demography. The Government is to be congratulated upon the selection that has been made. It may be found in practice, however, not altogether satisfactory that most of these experts have been placed in the technical committees and not on the Royal Commission itself. This may have been thought necessary on political grounds, but, nevertheless, the relegation of the scientific personnel to positions where they may not take part in the study and discussion of the broad issues is not perhaps a very wise arrangement.

The problem of human fertility, though it may appear simple to the casual observer, involves a great many extraordinarily complicated aspects—statistical, medical, social and economic. The Commission, although widely representative as it is, does not include among its membership many recognized students of demography. The Swedes, when they organized their population inquiry, foresaw this particular difficulty and arranged their committees accordingly. Perhaps in the case of Lord Simon's Commission, the problem may be overcome by a

close co-ordination of the work of the main body and its technical committees. This will be necessary unless time is to be wastefully expended on uninstructed debate.

The Commission's terms of reference are exceptionally comprehensive. It is to concern itself with the facts relating to the present population trends in Great Britain, the causes of these trends and their probable consequences, and finally to consider what measures, if any, should be taken "in the national interest" to influence the future trend and to make recommendations.

It is clear that the first task of the Commission will be to establish, and agree upon, the facts. Thus, in the first instance, much will turn upon the work of the Statistical Committee under the chairmanship of Prof. A. M. Carr-Saunders. Before any attempt can be made to extrapolate existing trends—even into the near future—the Committee will doubtless wish to ascertain what has been happening since the first (and only) fertility census for England and Wales in 1911. It has been pointed out that a 60-year decline in the birth-rate was arrested in 1933 and that, as the Minister of Health stated in the House of Commons in July 1943, the rate has since increased. But this does not necessarily mean that there has been a rise in fertility since 1933. The crude birth-rate is a very imprecise measure; it does not take account, for example, of changes in the number of women in the reproductive age groups and the proportion of such women married at each year of life. Due, of course, to the absence of data of this kind, there has been, not unnaturally, some divergence of opinion between different authorities as to the trend of fertility during the past thirty years.

From the statistical information so far made public, it may broadly be said that, before the War, the net reproduction-rate for England and Wales was approximately 0·80; in other words, the number of female births fell short by 20 per cent of the number which, other conditions being equal, would be required to replace in the next generation the women of reproductive age in the present generation. What of course is of paramount importance is the contribution made by women of different ages to this total replacement-rate. What changes have occurred, and are occurring, in the fertility-rates of women aged (say) 20–25, 25–30, 30–35 and so on, according to the proportions married, length of marriage and other factors? Is the present birth-rate being buttressed by an undue proportion of first births to young married women? Or does the rise in the crude birth-rate presage a shift in fertility in favour of larger families to older women? These are the type of problems which it will be essential to investigate if the Commission's work is to rest on any scientific basis.

But these are not by any means the only statistical questions which must come before the Commission. They are, after all, only national averages; and such averages may mask widely different social patterns. Next in order of importance then, as a preliminary to any study of causes and consequences, is the problem of what is known as 'differential fertility'. The reproductive behaviour of various social groups has for long been known to exhibit considerable differences. The inverse association of fertility with social and economic status has for many years been a characteristic of Western civilization. The census for England and Wales taken in 1911 showed, roughly, that the fertility of unskilled workers was about 80 per cent in excess of that for the highest social group. What has happened since 1911? Has the considerable fall in the national crude birth-rate during the past thirty years meant an equalization of the class-rates, or has the decline been disproportionately distributed over the various social and occupational groups? Furthermore, have the regional differences in fertility developed in a similar manner?

If and when the Commission reaches the stage of considering recommendations to reverse the present deficiency in births, the answers to these questions must, it seems, influence their deliberations. Quite clearly different instruments will be needed if some groups in the community are more than replacing themselves while others are far below replacement level, instead of a situation where uniformity in fertility behaviour is generally widespread. Questions of incentives to parenthood, such as a system of flat-rate or graded family allowances, are bound up with the nature of present-day class fertility patterns.

The initial labours of the Commission must, therefore, rest mainly with the Statistical Committee. Some of the information that is needed can be made available, no doubt, by the Registrar-General's Office from the results of the Population (Statistics) Act. But other essential data which are lacking (such as knowledge of class fertility) can only be obtained by fresh inquiries and additional research. It is not clear from the Government's statement whether it is intended to survey and report on what facts are already available, or whether some of the gaps in our knowledge about human fertility are to be closed. It is to be hoped that the Government will not, for the sake of speed, reject proposals for gathering fresh information vital to any adequate survey of such a fundamental problem. It will be better to have a good report in five years time than to appoint another Royal Commission in 1954.

It is stated that the Commission will, at a later date, take evidence on the more general aspects of the inquiry. To enable such evidence to be soundly based, it seems essential that any new statistical material should be made generally available for outside study. It is at this later stage, when the statistical ground has been covered, that presumably the Economic and the Biological and Medical Committees will be actively engaged in studying the problems of causes and consequences. The latter Committee may perhaps at an earlier date be occupied with the much-debated problem of fecundity, that is, the physiological capacity to reproduce.

Some time must elapse, therefore, before the Commission can come to grips with the problem of raising the average size of the family. This issue covers an immense field, and includes practically every aspect of social life from child welfare to education, maternity

provision to family budgets, employment policy to migration, housing to marriage barriers and much else besides. The Royal Commission, in surveying all these factors, will have the advantage of the great amount of research, reflexion and preparation that has gone on in Government Departments in relation to reconstruction. It will be unfortunate if post-war decisions on reconstruction do not take account of the work of the Royal Commission. But as reconstruction must be a process of growth, depending upon the characteristics of the transitional period from war to peace, it may not be too late to shape our post-war plans to influence Britain's demographic future.

THE FOUNDATIONS OF THE DEEP

The Floor of the Ocean
New Light on Old Mysteries. By Prof. Reginald Aldworth Daly. (The Page-Barbour Lectures at the University of Virginia, 1941.) Pp. x+177+12 plates. (Chapel Hill, N.C.: University of North Carolina Press; London: Oxford University Press, 1942.) 15*s*. 6*d*. net.

UNTIL the interruption enforced by the outbreak of the War, investigations of the ocean floor and its foundations were proceeding apace with steadily increasing success. In three lectures delivered at the University of Virginia in 1941, and now made available to all in this attractively written and beautifully illustrated volume, Prof. Daly presents a progress report of the detective methods used in probing the secrets of ocean geology and of the spectacular results so far achieved. The three chapters of the book deal in turn with (*a*) the composition and thickness of the sub-oceanic crust and the nature of the underlying substratum; (*b*) the islands, mountain structures and oceanic deeps which diversify the relief of the deep-sea floor; and (*c*) the submerged continental terraces and the mysterious 'canyons' or gullies of the continental slope. The book summarizes clearly and comprehensively a multitude of data not otherwise easily accessible; and it does much more than this, for the author has himself made notable contributions to his subject.

It is pointed out that the detailed investigation of the sub-oceanic crust from records of 'near' earthquakes must await the establishment of an adequate network of seismographic stations located on oceanic islands. Meanwhile, however, the study of long waves (recorded at continental stations after passing through the sub-oceanic crust) suggests in a general way that the rock underlying the central Pacific down to a depth of fifty miles or so is crystalline and has the composition of basalt, and that similar material underlies the other oceanic regions with here and there a thin and patchy covering of sial. The basaltic layer continues beneath the sialic layers of the continents, but, it is thought, with a considerably reduced thickness. From other geophysical evidence, as well as from the geological evidence provided by recently glaciated areas, it is inferred that underlying the basaltic layer there is a very thick substratum of exceedingly weak material. Two working hypotheses are then introduced: that the substratum has the composition of periodotite, and that it is weak because it is too hot to have crystallized. Such a glassy layer would react to earthquake waves as if it were solid, while behaving like a highly viscous liquid towards stress differences of longer duration.

The earth model now favoured by Daly is consistent with a wide variety of phenomena, including the support of great volcanic cones by the strength of the crystalline crust; but it still fails to account satisfactorily for the volcanic activity which built up those cones. Daly's earlier view was that volcanic islands, like the basaltic volcanoes and plateaux of the continents, were fed from a world-circling basaltic layer of which the deeper levels were glassy and therefore eruptible when tapped by fissures. But the idea that the present temperature at the base of the basaltic layer is everywhere high enough to maintain it in a glassy state has had to be abandoned, in face of recent accurate measurements of the heat flow from certain non-volcanic regions. Daly thinks it probable that there may have been a continuous glassy basaltic layer in former geological times, but if such a layer no longer exists it cannot be claimed as directly responsible for present-day vulcanism. The impasse is a very real one, and it should be clearly stated that the whole problem of volcanic activity seems now to be further than ever from an acceptable solution.

Other topics that are capable of more satisfactory treatment include coral reefs and atolls, and the interpretation of the belts of negative anomalies of gravity flanking the East and West Indies as long submarine mountain chains of probably Alpine complexity. Interesting reference is made to the cores of deep-sea oozes brought up from the Atlantic floor by the Piggott boring apparatus; but one misses a discussion of the possible total thickness of the deep-sea deposits. For a solution of this tantalizing problem we shall probably have to wait until sub-oceanic earthquakes can be recorded at nearby island stations. Pioneer studies of the thickness of the continental shelf sediments have already been successfully carried out by seismic methods.

More than a quarter of the book is a masterly description and discussion of the submarine 'canyons' and ridges which have been found to furrow the continental slope wherever its surface has been explored in detail by echo-sounding. These valley-like trenches and gullies have been excavated in the seafloor to depths of as much as 4,000 ft. below the intervening ridges, and some have been traced to depths of more than 10,000 ft. below sea-level. Many hypotheses have been proposed to account for their erosion; but only one, first suggested by Daly himself in 1936 and now more fully developed, appears to be reasonably satisfactory. During the glacial epochs the continental shelf was everywhere exposed. Waves and currents then churned up the muds of the outer part of the shelf and so gave rise to heavy undertow currents of mud-laden water which flowed down the continental slope and eroded chance depressions into deep channels. There is ample evidence, natural and experimental, that the process envisaged by Daly is a real and efficacious one and that its operation in glacial times is correctly dated.

Daly's latest book will be welcomed by a wide circle of readers. As always, he has much to say that is fresh and stimulating. Like Aristotle in an earlier age, he "adds boldness to genius" in synthesizing his facts into a world picture "with due regard to the steadily revised principles of a dozen other sciences".

ARTHUR HOLMES.

PIONEERING FARMING ON A WESTERN SCOTTISH ISLAND

Island Farm

By Dr. F. Fraser Darling. Pp. 224+26 plates. (London: G. Bell and Sons, Ltd., 1943.) 15*s.* net.

THIS book is a record of pioneer farming on the island of Tanera, one of the Summer Islands, lying a little way out from the mainland in western Ross-shire. Here the author and his devoted wife became the owners of an abandoned and ruinous house, and by sheer hard work, without, as the author says, any considerable bank balance to which to turn for comfort, have renovated the land with lime and basic slag, have repaired the ruined quay, have brought the garden again to life, and although their work is not yet completed, have changed the face of the land.

But this book is not concerned entirely with their days on what might be termed their home island, Tanera. There is a most interesting record of a journey to North Rona and a visit to Sula Sgeir. Readers of the author's previous book "Island Years" will remember that Dr. and Mrs. Fraser Darling remained on Rona throughout one autumn in order to study the home-life of the Atlantic seal. The second visit to that remote island fifty miles out into the Atlantic from Cape Wrath was made in the early summer of 1939, when (p. 81) the author found a colony of a thousand pairs of greater black-backed gulls nesting there. This must be the greatest colony of these large predatory gulls anywhere in the British Isles. Here he found the intestines of a bull Atlantic seal, which had died on that island the previous autumn, torn out by the gulls. The sun had dried these intestines—the author measured fourteen yards of them. The gulls had twisted them, time and again, in a fruitless effort to pull them to pieces, and in their twisted state the sun had dried the guts into a rope of great strength.

On Rona the author secured by flashlight what is probably the first photograph ever taken of Leach's petrel (p. 87) in flight.

From Rona a landing on Sula Sgeir was attempted, (p. 91) but was defeated by bad weather. But the author sailed round that rock in a motor launch, and estimated the number of gannets nesting there as four thousand pairs. It is likely that during the last four years the numbers have considerably increased, from Suleskerry Stack.

The main theme of the book is Tanera, an island homely as compared to Rona and no more than $1\frac{3}{4}$ miles from Baden Tarbat pier on the mainland. But even that island can be stormy enough upon occasion. There is a fine description (p. 173) of the great blizzard of January 18, 1941—a storm which I well remember in Skye, for the whole island was isolated by a greater depth of snow than had been experienced there for nearly thirty years. When they were half-way across to Baden Tarbat, the blizzard without warning swept in upon them:

"On Ben More Coigach there were huge plumes of driven snow flying from the several summits and ridges and shining in the sunlight in amazing beauty. Sea, sky and air—all reached a pinnacle of beauty in that moment, but contemplation of it was not my job. I knew that I gazed upon the coming of savagery of the elements, and did then what I have rarely done before: I turned back and berthed the launch before the harbour dried. . . ." When night came and the shutters were put up, "they could do nothing to prevent the terrible noise of the sea and the shaking and creaking of the little house. The byre was filling with snow when I went out to milk".

But even that blizzard was less severe than the one which followed on the night of March 26–27. The following morning, when Dr. Fraser Darling went out, what he saw (p. 176) was most remarkable. In his own words:

"When I went out in the morning I felt dazed, but things of interest revived me in a very short time. I was seeing things I might not see again—at least I hope I shan't. There were wrinkled crabs in the walled garden, not one but a dozen or so, and some were six inches across the carapace. Then I went into the park and found more crabs and many star-fish, and my collie found a ballan wrasse, weighing a pound and a half. The fish, and the crabs, are denizens of the sea just below low tide mark, and here they lay about the grass two hundred yards above the high tide mark. . . . Sometimes I wish I could have seen the great disturbance of the waters of the Anchorage which caused this to happen, and at others I feel that it was just as well to have been in bed."

That tremendous gale actually rubbed the bark from the apple trees, so that "it hung like the velvet from a stag's antlers in August".

Dr. Fraser Darling found (p. 195) that the rats which infest the island eat the pupæ of the green-bottle and bluebottle flies, and also the eggs of the Arctic tern, but are apparently afraid to enter a herring gull colony. The rats also make caches of potatoes up to 20 lb. in weight thirty or forty yards from the nearest row. When the author was trapping the rats he placed the carcases on a rock. The first three mornings the local ravens ate the carcases but never touched them after that: the author deplores the scarcity on his island of buzzards, which would have kept the rats in check.

The tree-planting experiments are interesting. Dr. Fraser Darling planted two hundred Corsican pines (*P. laricio*). Not one survives. We in the treeless north-west coast of Skye planted, as being hardy and salt-resisting, five hundred of these trees. Less than a dozen remain, twelve years after the experiment, and these survivors are barely existing and are no more than six feet high. Dr. Fraser Darling has found that Sitka spruce is the best tree, and this has been our experience also. But I believe that the best tree of all to plant would be Araucaria, the monkey puzzle, for, although not an attractive tree, it seems to be impervious to the salt-laden gales and grows absolutely erect and symmetrical in the most exposed island sites.

There is much interesting farming information in this book. To naturalists the author's account of how basic slag induced a strong growth of leguminous plants, and how those plants attracted the barnacle geese, is noteworthy. He describes in fine poetic prose, (p. 210) how the geese have lost their fear of him and now feed actually in the garden, allowing him to approach to twenty yards of them without fear. A remarkable photograph of the geese grazing illustrates this. A deficiency of lime is found in most soils of the Hebrides. Dr. Fraser Darling advocates the liming of the ground from the coral beaches. He is fortunate in having a coral beach within reach. Where I write, in northern Skye, the nearest beach of this kind (and this has already been almost worked out) is forty miles distant.

Dr. Fraser Darling notes that, in addition to the barnacle geese, many butterflies have been attracted to the land and the cliff's edge through the application of basic slag.

This book is indeed one of unusual interest, written by one who knows his subject as no one else at the present day. It is written simply, and in attractive prose, and is illustrated by some fine photographs, which have resisted the austerity production of war-time. This war production may account for the absence of an index. Seton Gordon.

DISK-HARROWING VERSUS PLOUGHING

Plowman's Folly

By Edward H. Faulkner. Pp. v+162. (Norman, Okla.: University of Oklahoma Press, 1943.) 2 dollars.

Where is the folly? Mr. Faulkner declares it to be with ploughmen who bury green manures, weeds and stubbles many inches below the surface. He is of the opinion that ploughing places such material out of reach of crop roots and creates a sub-surface "blotter" which interferes with capillary movement of moisture. He advocates the use of the disk-harrow as a means of incorporating such materials into the soil surface. If land is prepared in this way, and not ploughed, Mr. Faulkner is persuaded that crop yield may increase five- or ten-fold. By disking plenty of green manure into the surface he believes crop yields can be secured against the vagaries of the weather. According to his predictions, such crops will not be seriously affected by drought, nor, on the other hand, will they suffer in wet seasons. Land drainage would be not merely unnecessary, it would be detrimental to such crops. They would also be practically immune from the ravages of insect pests. Furthermore, Mr. Faulkner is confident that by using the disk-harrow in place of the plough, weeds could be much more easily controlled, provided this practice is adopted over the whole of a considerable area.

All these high hopes have sprung from Mr. Faulkner's experiences in growing vegetables in a garden in 1938 and in growing market garden crops, mainly tomatoes, in 1939 and 1940. No measurements are quoted, presumably because none was made. Mr. Faulkner's folly in committing himself to print on so slender a pretext is infinitely greater than that of any ploughman.

The heavy disk-harrow must be drawn by a tractor. No horse-drawn implement could incorporate a green crop in the soil surface as a tractor-drawn disk-harrow can do it. Mr. Faulkner's thesis that it is better to incorporate a heavy green crop in the surface layer than bury it at plough depth is not unreasonable, and results of independent field trials are quoted in which a fifty per cent improvement in yield was obtained. There is a case for investigation.

Investigation by field trial is inevitably a slow business. The experimentation must be sufficiently extensive both in time and space to cover normal variations in climate and soil. The desire to short-circuit this process is understandable, but should be held in check. The factors influencing plant-growth are many and complex. Patient investigation has greatly extended our knowledge of them in recent years. In the long run, agriculture is best served by using this knowledge to design field experiments.

We do not commit the folly of declaring that no benefit can be derived from disking that could not equally be obtained by ploughing. Traditional methods should be constantly under critical review. It may be that the plough has gained and maintained its favour with farmers on account of the neat appearance of skilfully ploughed land. The awards in ploughing contests have undoubtedly been based on the tidiness of the work. No proof has been sought, and certainly none has been obtained, that land judged to be best ploughed is thereby put in the way of producing the best crops.

Hitherto the record of green manuring in Great Britain has been chequered. On the whole the benefits predicted by its advocates have not been matched by practical results. Admittedly most of these green crops have been ploughed under, not disked-in. Now that tractor-drawn disk-harrows are more widely available, some enterprising farmers in Great Britain will no doubt try their hand at disking-in a green crop without waiting for the results of carefully controlled experiments. Farmers are cautious men, and are not likely to take very seriously the extravagant claims made by Mr. Faulkner. R. K. Schofield.

STARCH

Starch and its Derivatives

By J. A. Radley. (Monographs on Applied Chemistry, Vol. 11.) Second edition, revised. Pp. xii+558+47. (London: Chapman and Hall, Ltd., 1943.) 36*s*. net.

The second edition of this book is an improvement in many respects on that published three years ago. There has been a good deal of pruning of older work now obsolete, and many new chapters have been introduced which deal with a wider field of interest. Some of these have been contributed by recognized experts in the subject. An example of this is the section on the structure of starch which has been contributed by Prof. E. L. Hirst and Dr. G. T. Young. The reader is therefore introduced to some of the newer concepts of the constitution of starch derived from chemical evidence.

It is clear that the author has been at some pains to effect a considerable revision in this edition, and the result is that the monograph has gained in interest both for the general reader and for the expert. Even so, it cannot be said that the present volume provides much more than an introduction to a very complex subject, and, although the attempt has been made to give a critical review of the literature, the selection which has been made is not always well balanced or authentic in the conclusions which are presented. This is perhaps to be expected at this stage of the development of the chemistry of starch, where claims are often made which are conflicting, and where so much that has been written in the vast literature of the subject has to be discarded.

It can be said that the author has made a brave attempt to present in a concise form a very readable account of many of the reactions which starches undergo, and of the industrial and other uses to which they are put. Many readers will be grateful for the opportunity to use this monograph as a guide to the literature of the subject, including the original papers, and for a general survey which brings together much of the research which has been published and which is at present in progress.

GENETICAL CONTROL OF INCOMPATIBILITY IN ANGIOSPERMS AND FUNGI

By DR. K. MATHER

John Innes Horticultural Institution, Merton, London

ALTHOUGH the majority of organisms agree in showing some special control over their breeding systems, whether to encourage inbreeding or outbreeding, they display a great variety of devices by which control is achieved. In most animals the sexes are separate and so self-fertilization is impossible. In spite of this, however, a high degree of inbreeding can be achieved by controlled brother-sister mating, as in the grass-mite; or, on the other hand, inbreeding may be discouraged by various ancillary devices such as the production of unisexual broods or cyclical changes in sex. Discriminative behaviour in mating may also favour either outbreeding or inbreeding, or some combination of the two. In fact, it appears that the controlling devices are likely to depend for their working on any of the special characteristics and faculties of the organisms in question. This is strikingly illustrated in man, whose unique power of combining the transmission of rules of conduct, by means of what has been called tradition, with their enforcement by communal action, is used to govern mating in many different ways to give various degrees of outbreeding. Human matings may vary in advantage for non-genetic reasons in civilized and semi-civilized communities; but the occurrence of mating control even among the most primitive tribes shows that control must have arisen originally for genetical reasons[1].

In plants, as in animals, breeding control abounds, but it depends on a different set of devices. Plants are not mobile, and hence sex separation, or diœcy as it is here called, is not an efficient method of control, for it would involve an undue waste of gametes. Consequently, diœcy is relatively uncommon in plants, which rely on other means of governing the breeding system. Controlled inbreeding evidently may be achieved relatively simply, but outbreeding demands more complex devices[2].

First of all there must be some means of placing gametes from different individuals in appropriate juxtaposition. This may be done by growth of the parent individuals, as in fungi, but it often depends on the use of some intermediary, like water, wind or insects in higher plants. Thus we find adaptations to the use of such intermediaries, especially in the Angiosperms, where, for example, the means of attracting insects to the flowers are both complex and striking. But such adaptations, though clearly essential to outbreeding, will not of themselves suffice to secure its regular occurrence. The mere transport of gametes to another generative structure is not enough, because this structure may not be borne by an appropriate individual. Pollen may, for example, be carried by an insect merely from stamen to stigma of the same flower, or of a second flower borne by the same zygote in the Angiosperms. The plant must, in the last analysis, control the functioning of pollen for itself, if it is to exercise reasonable control of its own breeding. In the same way, though adjacent cells may not achieve fertilization in fungi, separate hyphæ of the same individual may grow together and mate unless some further restriction is imposed.

These further restrictions on inbreeding seem to be imposed in Angiosperms in two chief ways. There may be a time difference in the release of pollen and the receptivity of the stigma, such that certain types of mating are impossible. In protandry and protogyny this time difference will serve mainly to prevent effective pollination within a single flower, where, of course, it is most likely to be brought about; but it is unlikely seriously to hamper pollination between flowers of the same plant—a procedure which in the vast majority of cases has genetical consequences equivalent to those of self-pollination within a flower, as Darwin showed experimentally[3].

The second means of controlling effective pollination in Angiosperms is through the sorting out of the pollen, as delivered to the stigma, by the plant itself, with the prevention of functioning of inappropriate gametes. In fungi the same broad process is seen at work in the aversion, or at least ineffectiveness of contiguity, of inappropriate hyphæ. This general type of behaviour is described as incompatibility and appears to be widespread in the plant kingdom, though it is known by special names in some cases, for example, as heterothally in fungi. The underlying genetical and physiological mechanisms may vary too, but the main principle is always the same, namely, that there exist means whereby an individual, whether haploid or diploid, or even a single gamete, can discriminate for mating purposes among the functional gametes with which it might come into contact.

Incompatibility has been chiefly investigated in the fungi and in the Angiosperms. Discussion must therefore turn largely on the behaviour of these groups. In the former the haploid phase, generally speaking, dominates the life-cycle; though in the Basidiomycetes there is a compromise, a diplophase, with haploid nuclei and diploid cells. In the flowering plants, on the other hand, the haploid phase is so reduced as to be parasitic on the diploid. It is not therefore surprising, in view of the way in which special features of an organism appear to be used, where suitable, in the control of the breeding system, to find that while incompatibility is manifest between haploids in the fungi, the diploid phase plays its part in the Angiosperms.

In the fungi two levels of genetical elaboration may be recognized in the control of breeding[4]. The first involves control by a single gene of two allelomorphs, as in Mucor spp. and Ustilago spp. This prevents self-mating of the haploid, such as would lead to immediate homozygosis, but has no effect on the relative frequencies of homo- and hetero-zygosis following crossings of distinct haploids. In many of the higher fungi, however, greater elaboration is found, the genetical structure comprising one or more series of multiple allelomorphs, similarity for any one of which is sufficient to prevent effective mating. This is interpretable as an adaptation which, in addition to eliminating self-mating, decreases the relative frequency of mating between haploids originating from the same diploid or diplophasic zygote.

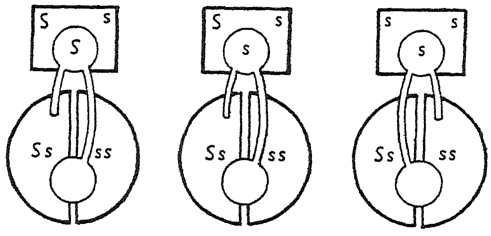
In Angiosperms self-mating of the haploid is ruled out by the separation of sexes between pollen and embryo-sac consequent on the extreme reduction of the gametophyte. The incompatibility mechanism is then concerned with the control of mating between haploids from the same zygote, which it can eliminate altogether and not merely reduce as in fungi. This elimination is achieved by the interposition of diploid somatic tissue, mainly in the form of the style, between pollen and egg. The stylar tissue, and perhaps also other somatic tissues of the ovary and

ovule, acts as a sieve which stops the tubes of certain genetical types of pollen, while permitting others to grow to successful fertilization. It may be noted that although within species the incompatible pollen is that which bears too close a genetical relation to the stylar tissue, the same system may also serve to exclude pollen which is genetically too unlike the female soma, that is, act as an isolation mechanism between species, as in Petunia[5]. Thus we may regard the stylar tissue as primarily a means of regulating the mating system of the plant, able to exclude both the too like and the too unlike (though, of course, other functions in adapting the flower to pollination by particular intermediaries have also developed). The female gametes themselves are protected and conserved in the sense that pollen with which these eggs would, as a general rule, give zygotes of inferior genetical constitution is prevented from achieving fertilization and so wasting the eggs. It is said that in some plants, like Gasteria[6] and the cacao[7], incompatibility manifests itself as a breakdown of development after fertilization. Such a situation can, however, scarcely be described as due to incompatibility in the present sense, for it omits the essential selective advantage of conservation of female gametes, and hence must have arisen in some other way. In fact, it is difficult to see how such a system could arise at all by direct selection. It must be a by-product of some other development[5].

The female haploid of the Angiosperms plays a purely passive part in mating discrimination, except perhaps in situations of the kind supposed to occur in Gasteria and the cacao. If the pollen tube can penetrate the female somatic tissue, it appears not to be repelled by the haploid organs of the embryo sac, and so encounters no further barriers to success. The diploid phase has taken full control on the female side. This is, however, frequently not the case on the male side. In incompatibility of the type first described in Nicotiana and Veronica, and now known to be widespread[8], the reaction is one between haploid pollen and diploid female soma. In all clear cases the genetical control is by a series of multiple allelomorphs, which act in such a way that pollen carrying an allelomorph also present in the stylar and related tissues is discriminated against. Pollen carrying an allelomorph not present in the female soma is not handicapped. It is characteristic of these systems, as of the genetically more elaborate fungi, that there should be a long series of allelomorphs, concerned with normal operation.

There are, however, also cases of Angiosperms in which the pollen grain is not autonomous in incompatibility. These are mainly afforded by heterostyled plants, though *Capsella grandiflora*[9] shows the same property without any morphological variation. In Capsella and distylic plants, such as the many dimorphic Primulas, the reaction of the pollen is most simply regarded as determined by the genotype of the soma which bore it. In Primula species, for example, the thrum type is heterozygous, *Ss*, and the pin type homozygous, *ss*, for the controlling gene. The *s* pollen of a thrum fails on an *Ss* style, where the *s* pollen of a pin is successful, but is successful on an *ss* style, where the pin *s* pollen fails. In other words, the male and female somata must be genetically unlike for success, the genetical constitution of the pollen being immaterial (Fig. 1.)

This simple interpretation breaks down with tristylic species, such as *Lythrum salicaria*, for here the position of anthers and stigmata in the flowers comes

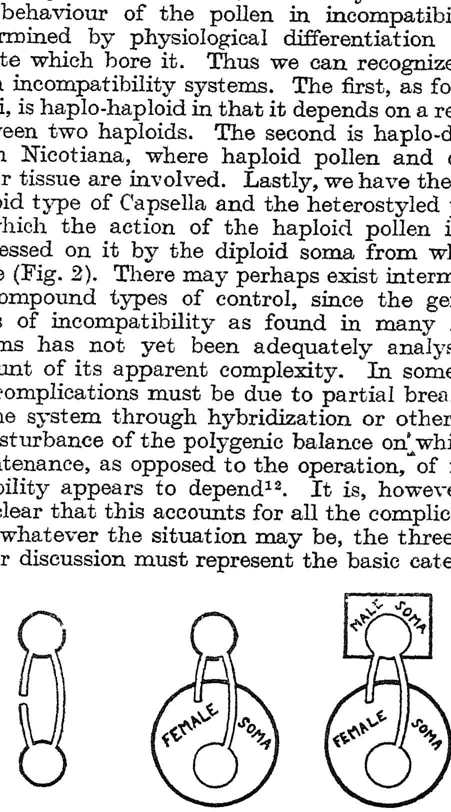


Thrum *Ss* Pin *ss*.

Fig. 1. Diplo-diploid control of incompatibility in Primula. Success or failure of the pollen (upper circle) in fertilizing the egg (lower circle) depends on the relations existing between the genotypes of the male soma (rectangle) and female soma (half circles). The genotype of the pollen itself plays no part in determining the reaction.

into play in a more striking way. A given flower produces pollen at two levels and each level has its own characteristic and distinct properties in incompatibility[10]. Thus the effect on pollen behaviour of the male somatic genotype is not so important as the immediate effect of the male soma where the pollen is borne. The behaviour of certain homostyled types of *Primula sinensis* suggests that the same mechanism may be operative in distylic species[11], but here, however, differentiation between the two possibilities is not final.

Whatever the mechanism of action of the male soma may be in such cases, it is at any rate clear that the behaviour of the pollen in incompatibility is determined by physiological differentiation of the zygote which bore it. Thus we can recognize three main incompatibility systems. The first, as found in fungi, is haplo-haploid in that it depends on a reaction between two haploids. The second is haplo-diploid, as in Nicotiana, where haploid pollen and diploid stylar tissue are involved. Lastly, we have the diplo-diploid type of Capsella and the heterostyled plants, in which the action of the haploid pollen is that impressed on it by the diploid soma from which it came (Fig. 2). There may perhaps exist intermediate or compound types of control, since the genetical basis of incompatibility as found in many Angiosperms has not yet been adequately analysed on account of its apparent complexity. In some cases the complications must be due to partial breakdown of the system through hybridization or other cause of disturbance of the polygenic balance on which the maintenance, as opposed to the operation, of incompatibility appears to depend[12]. It is, however, not yet clear that this accounts for all the complications. But whatever the situation may be, the three types under discussion must represent the basic categories,



Haplo-Haploid. Haplo-Diploid. Diplo-Diploid.

Fig. 2. The stages in control of incompatibility by the diploid phase. In the haplo-haploid, incompatibility depends on the genetical relations of two haploid cells; in the haplo-diploid, on the genetical relations of haploid pollen and diploid female soma (the egg being passive); and in diplo-diploid on the relations between male soma (the reaction type of which is impressed on the pollen it bears) and female soma.

and all the cases which are fully understood fall into one or other, with or without some breakdown.

As we have seen, normal operation of the haplo-haploid and haplo-diploid types is characteristically controlled by series of multiple allelomorphs. The diplo-diploid, on the other hand, has a simpler genetical control. There are never more than two allelomorphs of any one gene operative in the normal system (multiple allelomorphism may be involved in breakdown), though a little genetical elaboration may be introduced by the operation of two loci, as in Capsella and Lythrum[13]. My colleague, Dr. D. Lewis, has pointed out that this difference in genetic control is probably a reflexion of the two types of gene action involved. In the haplo-haploid and haplo-diploid each allelomorph may be regarded as essentially individualistic in action, for only a single allelomorph can be operative in any one reaction. Hence no question of combining and co-ordinating the action of two allelomorphs arises, in the way that it must with the diplo-diploid system, which may thus be physiologically restricted.

The three types of incompatibility systems form a series of increasing control by the diploid phase. Is there any corresponding increase of efficiency and advantage to the plant ? It is not difficult to see that the intervention of the diploid phase on the female side is advantageous. Haplo-haploid control can prevent inbreeding at the first and most extreme level, namely, self-mating of a haploid leading to immediate homozygosis ; but it can never wholly eliminate the occurrence of inbreeding, at the second or zygotic level, by mating of haploids from the same parent zygote. This may be of lesser importance in fungi, where the spores of a zygote are broadcast widely ; but in an Angiosperm it is a matter of considerable moment because self-pollination, leading to mating of male and female haploids from the same zygote, may be unduly common unless restricted. The interposition of the style in the incompatibility system allows of complete elimination of this contingency, if advantageous, with the result that inbreeding is controlled at the zygotic level.

The second difference in the degree of diploid control, that on the male side, seems to lead to no increase in efficiency. The suppression of inbreeding at the zygotic level is achieved by the action of the diploid style, and given free dispersion of pollen and seed the prevention of self-pollination ensures maximum outbreeding. Breeding systems must be regarded as essentially adjusted to controlling the degree of heterozygosis of the population[14], and the maximum heterozygosis obtainable for all the genes of an organism by this means alone is that given by random mating. Higher values of heterozygosis can be obtained if mating of homozygotes is restricted in highly specific ways, but these are extremely unlikely to be found in Nature for any but special genes such as those which control the breeding systems themselves. Permanent heterozygosis also occurs in Oenothera, for example, but balanced lethals and ring-formation are involved in the mechanism, which thereby does not depend solely on the breeding system in the way we are discussing. Thus, so far as mating control is concerned, inbreeding in flowering plants is largely a matter of self-pollination. Indeed, as measured by Wright's inbreeding coefficient[15], the rate of inbreeding may be calculated to a first approximation, the adequacy of which depends on the adequacy of seed and pollen dispersal, from measurements of the natural rate of self-pollination.

From this point of view the haplo-diploid system is no less efficient than the diplo-diploid, for both can give maximum outbreeding, namely, effectively random mating in all but the smallest populations. Indeed, where pollen and seed dispersal are not free, haplo-diploid systems may have an advantage over the diplo-diploid as we know it, since the multiple allelomorphs of the former permit somewhat freer mating between non-sister zygotes than between sisters. This superiority of control at the third, or sibling, level of inbreeding seems, however, likely to be an advantage too trivial to warrant consideration at the present stage of analysis ; but a second potential disadvantage of dependence on two allelomorphs is more serious. In distylic plants, with one gene of two allelomorphs, any individual can mate successfully on the average with only one half of its fellows. In tristylics this fraction is raised to something like two thirds, but in the haplo-diploid system, with many allelomorphs, the effective fraction must approximate closely to unity. Thus mating efficiency is higher and gametic loss lower with a haplo-diploid control, though the gametic loss is perhaps somewhat reduced in the diplo-diploid type by the heterostyly with which it is so regularly associated.

The diplo-diploid system has, however, one compensating advantage, in that the haplo-diploid requires a minimum of three allelomorphs for its operation whereas the diplo-diploid requires but two. For this reason it may well be that the genetical situation necessary for the origin of a diplo-diploid control is simpler and more likely to occur than that for the haplo-diploid. In view of this it seems that diploid and haploid controls of the incompatibility reaction on the male side cannot on balance differ markedly in the relative advantages which they carry. This is in sharp contrast to the corresponding situation on the female side, where the advantage of diploid control by the interposition of the style is always clear in affording the possibility of eliminating mating between both the too like and too unlike. It is thus not surprising that the structure through which diploid control on the female side is exercised should be a universal feature of the higher plants, whereas there is apparently no corresponding uniformity of control on the male side. Perhaps if a form of male control should arise, combining the ease of origin of the diplo-diploid type with the efficiency of operation of the haplo-diploid, it would supplant both the existing types. Such a system would presumably use both the multiple allelomorphs of the haplo-diploid and the co-ordination of gene action necessary to impress a somatically determined behaviour on the male gametes in the way shown by the diplo-diploid. It is, however, not yet clear how, or even whether, such a system is a developmental possibility.

THE ILLUSION OF PERSONALITY*

By H. G. WELLS

THE integrality of the individual in the higher Metazoa is a 'biologically convenient delusion'. The expression 'psycho-analysis' implies a mental unity which can undergo analysis. This is the delusion. The reactions of the human machine are loosely linked behaviour systems, participating in a common delusion of being the self. Most lower animals react to stimuli without hesitation. As we ascend the scale *inhibition* appears. There is no longer a mere algebraic summation of stimuli. There is reference back to a storage organ, a 'brain'. According to the record of that storage organ, the organism, not as a whole but as much of it as is affected by the recorded stimuli, reacts. Circumstances may have changed and it may act disastrously, or it may 'profit by experience'.

The *conception of self* appears most evidently in gregarious animals, which have to conduct themselves with regard to the flock or pack. The sub-men seem to have been gregarious running animals, less like the solitary great apes than the baboons. Self-consciousness and a conception of other individuals as consistent persons are necessary to gregariousness. The self-conscious social individual, *whatever it does and however much of it does it*, will ascribe its behaviour to its self, the same self, in continuous operation.

A man awakening from sleep imagines, when he has rubbed his eyes and yawned, etc., he is 'all there'. He is not. The evanescent impressions of dreamland give way to a more vivid reaction-memory-and-event-system which has established a by no means perfect control over what are called the voluntary muscles of his body. Body holds mind together and not mind body. The body goes as the dominant system in the neuro-sensitive apparatus directs, but other reaction systems are either deflecting or ousting the dominant system.

There are endless variants of 'John Smith'. He will admit in ordinary speech that he 'has his moods' and sometimes 'forgets himself'. It is John Smith No. 214, John Smith who had a dispute with his employer yesterday, who wakes up, the indignant employee. He rehearses a spirited conversation with his 'gov'nor'. He sees his wife's portrait on the mantel and succumbs to resentment and jealousy. The recalcitrant employee is simply not present. John Smith, under control of No. 618, goes down to breakfast in a dark, unloving mood. All the Smiths, from No. 1 to No. 5,000 or No. 5,000,000, have a common belief that John Smith is really one person, because they are not only all aboard the same body, but also built round a similar conception of himself, his *persona* as Jung has it. *In fact, they are a collection of mutually replaceable individual systems held together in a common habitation.*

If the systems vary widely, John Smith is a moody man. If still more widely, you have at last a 'double personality'. Whatever system dominates at the time owns John Smith and believes itself to be wholly and solely John Smith.

Conduct systems of reaction require a fable to hold our *selves* together and put them over to others. The neuro-sensitive apparatus in social animals cannot do a thing and forget, cat-fashion. Our conduct systems, whenever they invade simpler systems of reaction in us, set about attacking the independence of these other impulses and drawing them together. They go about like governesses, drill-sergeants, imposing an impossible uniformity of discipline upon the mute unconscious elbowing of our other drives and reactions.

In order that the *persona* should be as consistent as possible in its autobiographical effort, these conduct systems, which concern themselves with the reputation of a human body, ignore aberrant impulses, push them away into what the analyst calls the unconscious, that is, a multitude of reaction systems out of contact with the main directive system. The psycho-analyst says they are below in a dungeon ; the behaviourist says they are at large outside. The contradiction is flat.

Jung called this excluded stir the *anima*. It may contrast markedly with the material in the *persona*. It stirs, says the psycho-analyst, beneath the conscious life. It skulks, says the behaviourist, on the edge of the waking life.

That the integrality of the human individual is illusory does not sweep aside continuity from life. The individual belongs to his species, which existed before he appeared in the world, and will outlast him. Generally a man does not realize that. He may refer himself to a family, to a tribe, to a school, to a real or imaginary 'race', to a creed—indeed to a vast variety of larger aggregations. He may fluctuate in his terms of reference. So he thinks and feels. The biological reality is that while he can interbreed with every variety of human being, he goes on as a unit in the whole species, and, whatever frame of community he adopts, it can, from the ecological point of view, have no narrower boundary than the species. Every individual is in the nature of a unique experiment. There is no experimenter nor question behind it ; it is an unpremeditated experiment.

It may be rejected at once ; or it may have survival value in itself. By surviving it changes the totality of the species by its individual difference. In the generality of cases the difference is slight, and such individual cycles are called *normal*. Their collective effect is that of confirmatory experiments.

A marked and sudden difference is called a variation. The causes of a variation will almost certainly be acting not merely in one case but also upon groupings of similarly situated genes. So long as the individual variation has the qualities that enable it to survive and reproduce itself it will do so.

There is no benevolent bias in that survival. A species may go on varying and surviving through its individuals for a long time, although it is accumulating a variation that will disarm it against some conclusive danger. Most variations have no survival value at all ; but when a species has drifted into disharmony with its surroundings—and that is the case with ours at the present time—then abnormalities which would have been suppressed in the humdrum days of security may stand a chance of temporary establishment. Palæontology shows repeated evidence of a sort of flurry of abnormalities before the collapse and obliteration of some dominant group which has outstayed its welcome. This seems to be the case with man to-day.

From its first appearance, the human animal was too widespread and too thinly spread to produce a

* An abridgment of a thesis on "The Quality of Illusion in the Continuity of the Individual Life in the Higher Metazoa, with particular reference to *Homo sapiens*", accepted for the doctorate of science of the University of London. Copies of the complete thesis are available to scientific institutions free of charge ; otherwise it is two guineas unsigned, which will be devoted to the propaganda of the Natural Rights of Man, of which Mr. Wells is acting secretary.

homogeneous *Homo sapiens* throughout the earth. There has been more homoplasy and less of diffusion in Homo than is commonly believed.

Migrations began only in the past ten thousand years or so, when the social structure had developed means of conquest and exploitation. At a far remoter period exiguous human races ranged seasonally over wide territories, incapable, for lack of transport or organization, of sustained aggression or enslavement. The seasonal movement of gregarious food animals, horses, cattle and the like in response to pasture may have led to seasonal gatherings of these far-flung tribes from considerable distances, with little or no spirit of feud or aggression.

The leavings of Solutrean men suggest a gregariousness in which the individuals were more self-reliant and socially tolerant than their descendants. These early nomads exchanged goods at these primordial fairs, as the distances of many early artefacts far from their sources testify. With the dispersal of the food beasts this human gathering dispersed again, with quite possibly a woman or so and an artificer going off with a new party. He or she would not need to learn a new language, when grunts and gestures remained the language of mankind.

Time estimates of these periods defeat even geologically trained imaginations. Our grip on big quantities is a feeble one. We have got beyond any other animals by checking with our digits, but our sense of a hundred is foggy, and few will agree whether a crowd was a thousand or three thousand strong. Beyond these limits we *concertina*. We have a 'gibus' sense of time. A thousand years is a huge succession of yesterdays beyond our clear apprehension. If we reflect on the changes in social life since the Christian era, we may achieve an intellectual if not a realistic comprehension of the remoteness of these wanderers from whom we spring. Many people believe that our ancestors were like the Australian aborigines. These 'primitive peoples' are imagined as having been marking time for a hundred thousand years. But in that interval they have been subjected to climatic changes, changes of food, new environments. They have experienced dark ages and phases of recovery. Anthropologists underestimate the intervals in which these systems have decayed and revived and changed and become something quite different. The 'primitive' Australian *talks*, and he has a complex grammar. He betrays traces of admixture, and, if we bring geographical shifting into consideration, we are forced to conclude that in the past there must have been trading, a 'pigeon' language, and ideas and imitative stimuli from other drifting peoples. One may doubt if one can exaggerate the mental remoteness of these creatures whose lives are the basis of our thought and feeling. The makers of eoliths and of Chellean implements gave place to Acheuleans, to Mousterians, to Aurignacians, Solutreans and Magdalenians. Meanwhile every species of large animal contemporary with the Acheulean had become extinct. Can we imagine, then, that the ascent of man has been simple and straightforward from Neanderthal to Beckenham, Paris and the Riviera ?

We make our way painstakingly to the fact that the mind of ancestral man was essentially unlike ours, and that the species was living under conditions still mostly unimaginable. He was not only different from anything human we can talk to, but, from the very beginning, he was also different *inter se*.

A species is a species so long as it can interbreed and its kindred varieties, however divergent, can be recognized. There never was an original dog. Dogs are anything but select in their emotional phases. If an end came to dog fanciers, Canis would go back to a variety of mongrels, reflecting the regional opportunities in which they found themselves.

Gregariousness is a subordination of the individual to the herd. The individual merges into a wider synthesis, a vast sentient web overspreading many acres; becomes shareholder in faculties always awake, eyes that see in all directions, ears and nostrils that explore a broad belt of air; a super-individual occupying every bit of ground whence the approach of an enemy can be detected. Each individual receives a maximum of security at the cost of a minimum of individual animation. When an animal which has been accustomed to a gregarious life is isolated, it feels itself exposed to danger from every part of the circle around him, except the one point on which his attention is momentarily fixed. His glance is restless and anxious, and is turned in succession to different quarters; his movements are hurried and agitated, and he becomes a prey to the extremest terror. The blind instincts evolved under those conditions have been deeply ingrained into our breed, and they are a bar to that freedom the forms of modern civilization could assure. A modern community must be held together by stronger forces than are derived from the purely gregarious instincts. It cannot be a mob of slaves, clinging together, incapable of self-government and begging to be led; because it will always be led to disaster. It must consist of vigorous, self-reliant men, knit to one another by a strong, tense and elastic community of will and understanding.

The personal life of the individual will still continue, held together by the individual body. Within its conditions that may be a very intense and passionate existence. Many of the bodily phases that constitute John Smith may be preoccupied with sex. The sexual stir of the contemporary Homo is renewed monthly, unlike so many of the larger Eutheria, which have their annual rut. These phases are dependent upon the secretion of gonads, which again seems to be determined by the fluctuations of innate rhythms under climatic and correlated physical influences.

There has been an enormous and biologically unserviceable over-development of those aspects of life in the handy and intelligent Primates. The release of hand and brain by the adoption of the erect attitude during the human dawn, and the revival or continuation of some primitive monthly breeding cycle among the sub-human and human series, stimulated a recurrent or almost continuous interest in the orgasm that is only too manifest in a cageful of monkeys or any over-fed and idle social group—both confined and unemployed groups. But while the monkey's interest is unabashed, contemporary man is in a state either of defiant indulgence or passionate suppression that disorders all his social life. Christianity, Islam and Judaism are all phallic religions, and 'morality' over a large part of Christendom means nothing more than values attached to sexual behaviour.

But we do not know how long this stress on sex as 'morality' has lasted. Dawning man, except under deprivation, may have been as shameless and casual as a monkey. Those primordial fairs were amiable corroborees, free of competitive or possessive ideas. We may describe man, in those sparse days, as under-

sexed. The male and the female of the species excited one another and achieved a mutual or substitutional relief; it was all over in no time, and that was all about it. The manner in which the sexual urge lies in wait, so to speak, and seizes upon and makes use of any unemployed mental energy in *Homo sapiens* has still to be worked out in detail.

There have been and still are wide and rapid variations in the relationship-phases of men and women, and nowadays a woman will be either a subjugated meretrix or a hard-minded and responsible equal, just in the measure that her sexual impulses and status dominate or are secondary in her *persona*. The decision rests upon womankind and the atmosphere they will create.

Every living thing, in obedience to its hormic urge, seeks to assert itself over other things that move about—over other life or over inanimate things that are imagined as having life. "This," in effect says life, emerging to a consciousness of others, "is not going to beat me." This primitive uneasiness to reassure oneself that one has the upper hand of the not-me is still far more persistent than any other urge. We assert these selves through a huge miscellany of claims. The claims we make depend upon our upbringing and the ideas imposed on us. We pride ourselves on 'race', country, class, family, 'set' or dollars, intuitions, exceptional muscles or remarkable characters. We gravitate to the groupings in which these are key values.

Man in his dawn was certainly not so collectively maladjusted as the man of our own time. Contemporary man *en masse* is definitely a degenerate creature, in the sense that he presents no collective resistance in the face of change. He experiments only feebly in adaptation; he persists in his follies.

But since we have some two thousand millions of him varying about the average cases *of any particular quality*, whatever it may be, the exceptional instances are likely to have a wider range than in any previous period. These exceptional types will include, among others less biologically favourable, types of self-forgetfulness in some impersonal interest.

The factor in the individuals of this emergent *élite* is a development of the natural curiosity, the picking and searching hands and eyes of our ancestors. The dominant phases of the unrestrained man, as distinguished from the suppressed individual in our now disintegrating modern communities, are those of an inquirer and maker. His unrestrained phases discover an innate desire for mastery; in invention (artistic or 'practical') and construction, according to his aptitude. The profounder disposition of mankind is to make, and to sublimate self in the discovery, each man, of his own idiosyncratic creative possibility.

In the case of an intellectual *élite* there will be recurrent phases in their lives when an ecstasy of discovery will possess them. They will stand "silent upon a peak in Darien". They will be looking upon something, hitherto hidden, which will now be the property of all mankind. They must descend again from that great moment into the shadow of their personal selves, but the achievement will remain as an enduring contribution to the human synthesis.

The spreading realization that personality is illusory will not abolish the practical reality of individual living. This warp and woof of hallucination provides the fabric on which lives are lived, just as the cinema screen supplies the fabric on which personal dramas are played out. To realize that the drama is hallucinatory will be to escape from ultimate 'explanations' of life, from priestcrafts and mental muddles that have embittered human relationships hitherto, but it will not release human beings from 'conduct'. It will, however, lift them into a new atmosphere, and mitigate profoundly the confused motivation of that long "Martyrdom of Man" which is now drawing to an end.

OBITUARIES

Sir John Farmer, F.R.S.

By the death of Sir John Farmer on January 26 biology has lost an outstanding figure, one who did much for the development of botany and for the extension of its applications.

John Bretland Farmer was born on April 5, 1865, at Atherstone and was for a time at the Atherstone Grammar School, but was later educated privately. A country upbringing and a knowledge of the farmer's outlook was of great value to him in his later efforts to use botany for the advancement of agriculture. He went to Magdalen College, Oxford, in 1883, and took a first-class in the Honours School of Natural Science in 1887. In that year he was appointed demonstrator in the University, for Bayley Balfour, who was then Sherardian professor of botany, early recognized Farmer's intellectual gifts and fostered his botanical development in every way. Farmer would often speak in warm tones of the inspiring influence of his old teacher, who was both botanist and gardener. In 1889 he was elected to a fellowship at Magdalen.

When Huxley retired from the headship of the Biology Department of the Royal College of Science at South Kensington the chair was replaced by two assistant professorships, the botanical one being filled by the late D. H. Scott. When Scott retired in 1892 he was succeeded by Farmer, the position being raised to a full professorship in 1895. Farmer remained at South Kensington for thirty-seven years, retiring only in 1929.

Farmer's long period at the Royal College of Science (later to become an integral part of the Imperial College of Science and Technology) was one of remarkable development and expansion of the department. In Farmer's early years at South Kensington the department was housed in two rooms at the top of the building in Exhibition Road and the staff was a professor and one demonstrator. When he retired in 1929 the department occupied two large buildings in Prince Consort Road and consisted of five sub-departments, each with a professor at its head.

Farmer was not only a scientific investigator but also a man of vision who had his own distinctive idea as to the direction in which the department should develop. Fifty years ago academic departments of botany held aloof from the practical application of their subject. Farmer, however, early realized how much trained biologists (plant pathologists, geneticists and plant physiologists) could do not only for agriculture in Great Britain but also for the plantation industries overseas and for tropical agriculture generally. He therefore set himself to provide such a training in pure botany as would equip men for work in applied botany abroad. This aim he fully achieved and his students were soon occupying important positions in Colonial agriculture. Some measure of his success may be gathered from the

testimonial given to him on his retirement. Of the old students subscribing, fifteen were in India, ten in Africa, seven in the British West Indies, seven in the Federated Malay States and Borneo, six in Egypt, five in Ceylon and a number in Australia, New Zealand, Burma, Iraq and Japan.

In the pursuit of these aims Farmer did not, however, allow the torch of pure learning to be dimmed. He had wide interests in botany and published work in various fields, and he did distinguished work as a cytologist before the boundary between cytology and genetics had broken down. In 1907 he gave the Croonian Lecture of the Royal Society—of which he had become a fellow in 1900—his subject being the "Structural Constituents of the Nucleus and their Relation to the Organization of the Individual". He received a Royal Medal in 1919 and was a vice-president during 1919–21. Farmer was a writer of clarity and directness, qualities which he himself ascribed to a youthful drilling in Latin. He wrote several smaller books on elementary botany and with A. D. Darbishire edited the translation of "Die Mutations Theorie" by de Vries. He organized and during its early years was editor of *Science Progress*. He edited also the *Gardeners' Chronicle* during 1904–7 and for a number of years the *Annals of Botany*.

Farmer, with his broad scientific knowledge, his grasp of affairs and his powers of decision, was naturally in great demand where the organization of what might be called plant technology was concerned. He was a member of the small Inter-Departmental Forestry Committee, on the report of which the Imperial Forestry Institute was founded. He served on the Milner Committee, and played a large part in the establishment of the Imperial College of Tropical Agriculture in Trinidad. He was a member of the Advisory Council of the Department of Scientific and Industrial Research from 1920 until 1926, and it was during that period that the Forest Products Research Board was organized, and he was its first chairman. To the Empire Cotton Growing Corporation, especially in its early years, Farmer gave notable service. On behalf of the Corporation he and Mr. L. G. Killby visited Trinidad in 1925, and as a result of their report the Cotton Research Station was set up in 1926. He also gave invaluable advice and help when the Corporation established a postgraduate studentship scheme for the recruitment of its staff. Later he was to serve on a committee set up by the Secretary of State for the Colonies to inquire into the training of agricultural officers for the Colonies. Farmer, from his experience of the Corporation's scheme of postgraduate studentships, advocated a similar one for the Colonial Office. As a result of the Committee's report an entirely new scheme of recruitment for the Colonial Agricultural Service was established. Farmer's advocacy was of the greatest value, for the scheme brought about an almost revolutionary improvement in the qualifications of the Colonial agricultural officer. Farmer was active in many other ways—as a member of the Research Committee of the Rubber Growers' Association, of the Royal Commission for the Exhibition of 1851, and of the governing body of the Imperial College, on which he served from its establishment in 1907 until his retirement. He was knighted in 1926.

Farmer was a man built on generous lines both in mind and body. He stood well over six feet, and the big muscular hands of his large-boned frame were equally good at cutting a botanical section, tying a fly, or giving confidence on the rope to the tyro whom he was instructing in the craft of rock climbing; for he was botanist, fisherman, mountaineer and, not least, gardener. In all these pursuits Farmer was the born teacher, always ready to pass on his knowledge, and delighted if he could inoculate others with his enthusiasm. Farmer was a steadfast friend, and since to a knowledge of men and affairs he added the quality of 'allroundaboutness' of outlook, one could go to him in a difficulty with the certainty of receiving counsel of rare balance and wisdom.

V. H. BLACKMAN.

Prof. J. W. H. Eyre

BRITISH bacteriology and Guy's Hospital both lost an outstanding personality when Prof. J. W. H. Eyre, emeritus professor of bacteriology in the University of London, recently died at the age of seventy-five. Entering Guy's as a medical student in 1889, he qualified in the minimum time, graduated M.D., M.S., in the University of Durham and received his first hospital appointment. This initial experience as registrar in the Ophthalmic Department was an appropriate introduction to the delicate, small-scale experimental laboratory work to which he was later to devote his life. In fact, his first research, though ophthalmic, was essentially bacteriological, culminating in his description of tuberculosis of the conjunctiva which stands a classic to this day. At that time (1895) all hospitals, realizing the great future of medical bacteriology, were developing laboratories accordingly, and inevitably Eyre was attracted by this new trend. In 1899 he gave up eye work entirely for the post of bacteriologist to Charing Cross Hospital, where he became the first Ernest Hart Memorial Research Scholar and at once began to devise new technical methods, and showed such genius for the work that three years later he was invited to occupy the corresponding post at his own hospital. He never again left Guy's and there centred the whole of his remarkably industrious and productive career.

In 1905 he was invited by the Royal Society to join the Advisory Board of the Commission on Mediterranean Fever. Working overseas as chairman of the team experimenting in Malta he was associated with a number of results which did much to advance our early knowledge on Brucella infections and paved the way to their ultimate control. Returning home he resumed his former work of bringing law and order into the still somewhat chaotic state of routine bacteriological investigation, and shortly after published his standard work, "The Elements of Bacteriological Technique", which, when consulted to-day, shows us his pioneer conception of a remarkable number of modern methods. About this time he was elected a fellow of the Royal Society of Edinburgh. Soon, bacteriological diagnosis becoming more accurate, he found it possible to give his research a more direct medical bearing, and over this period he published with his clinical colleagues many case notes on infective disease.

Most notable, perhaps, was his work on the varieties of pneumococci associated with different respiratory infections, a true forerunner of later developments, and also his proof that much institutional dysentery was really of the Flexner type. Meanwhile the amount of work entering the laboratories at Guy's was increasing so rapidly that the Governors of the Hospital wisely decided to develop a new and completely up-to-date department. This they entrusted to Eyre,

giving him an entirely free hand, and the result was possibly one of his major contributions to his subject. For many years his laboratory stood as a model for others, both as to its design and its system of records, references and accounts. It was, in fact, still meeting every demand made upon it even at the time of his retirement twenty-five years later, a remarkable example of his exceptional skill as organizer as well as scientific worker. Its opening coincided with the outbreak of the War of 1914–18, and as might be expected, although the Department was never under direct Government control, a very large amount of work directly aiding the Services passed through it. Eyre's peace-time activities had brought recognition in the form of appointments as Erasmus Wilson Lecturer and Hunterian Professor at the Royal College of Surgeons and Milroy Lecturer before the Royal College of Physicians.

The moment war broke out he placed the facilities of the laboratory at the Government's disposal, and the first big work undertaken concerned the urgent task of systematically detecting the many typhoid and paratyphoid carriers returning from the British Expeditionary Force. Methods were standardized and compared and a complete system instituted which must have prevented many home outbreaks. In 1915 Eyre was appointed as a civilian pathologist in the London District Command, and co-operated in improving and selecting the various anti-enteric vaccines which later proved so successful in France. Then the second great war-time infection threatened, namely, cerebro-spinal fever, and his laboratory again was active in investigating both meningococcal carriers and acute infections. It is interesting to note in his reports of those days how he insisted, and was ultimately proved correct, that cerebro-spinal meningitis is primarily a septicæmia. A little later, these urgent investigations being over, Eyre turned his attention to the then somewhat inadequate bacteriological facilities available to the many semi-private military hospitals which were springing up all around London, and we find him displaying really astonishing energy as honorary bacteriologist to a very large number of them. Military, Royal Flying Corps, and American units were included, and the volume of personal work he must have got through at that period was enormous.

When the influenza epidemic attacked Great Britain, Eyre at once found himself involved in the investigation of the prevailing secondary respiratory tract infections and the possibility of preventing them by prophylactic vaccine. In this case he was particularly concerned with the New Zealand Forces, and at one period his Department placed half a million doses of vaccine at the disposal of the Army Medical Department of the War Office inside seven days. Records show how greatly this work must have reduced the incidence of complications. In April 1918 he was invited to join the Trench Fever Committee of the War Office and co-operated in proving this disease to be louse-borne, although the War ended before the exact nature of the organism could be determined. His final war-time contribution was as a member of the Chemical Warfare Committee of the Medical Research Council, the work of which guaranteed our preparedness in that sphere at least.

The return to peace conditions called for considerable departmental reorganization, and Eyre's was one of the first to get into its stride again. A rapidly expanding venereal disease clinic at his hospital brought new volumes of serological work, and he was concerned with many serial observations on the comparative value of the Wassermann reaction and the various flocculation tests for syphilis. Also Sonne dysentery was coming to be recognized as a real threat to institutional life, and one of the earliest fully recorded outbreaks was observed in his laboratory.

Having held a readership for many years, Eyre was in 1920 appointed professor of bacteriology in the University of London, and from then onwards his activities in medical societies and committees became even greater. He had been president of the Section of Bacteriology and Pathology at the British Medical Association meetings of 1933 and became president of the Royal Microscopical Society in 1920. Later he held the same office in the Hunterian Society and the Royal Institute of Public Health and Hygiene. He attended many overseas meetings and was well known on the Continent. His editorship of the English translation of Kolle and Hetch's "Experimental Bacteriology" was admirable.

Although the scientific world will remember Eyre chiefly as an inventor of technique, his colleagues at hospital always realized that he had considerable clinical gifts. He was always about the wards and his advice freely taken. He produced with Dr. Bosanquet a most useful little manual, "Serums, Vaccines and Toxins in Treatment and Diagnosis". The passing years never seemed to affect his remarkable energy, and his strong personality carried him along, always in harness, to the very end. An interesting appointment which he held for a good many years was that of bacteriologist to the Worshipful Company of Fishmongers, and he may be said to have thereby controlled the bacteriological purity of the nation's fish supplies, doubtless preventing innumerable epidemics. But this work had its essentially scientific side also, and he produced several beautifully illustrated monographs on the bacteriology of the edible molluscs.

His colleagues at Guy's will always remember the minute, neat, intensely active figure of "Johnny" Eyre. Everyone knew, honoured and loved him and, when he retired from the active staff of the Hospital in 1934, gave him a memorable farewell dinner. But he never entirely deserted his Medical School, and was seen about the laboratories less than a week before his tragically sudden death. Those who actually worked with him will greatly miss the inspiration which he always gave to them and his unfailing interest in the welfare of everyone ever connected with his old Department. There are many working in the medical laboratories of to-day who, for the excellence of their earlier training, owe him a very great debt of gratitude. F. A. KNOTT.

WE regret to announce the following deaths:

Dr. J. McKeen Cattell, editor of *Science* since 1894, and also of other American scientific journals, on January 20, aged eighty-three.

Mr. A. W. Clayden, principal during 1894–1920 of University College, Exeter, known for his reports to the British Association on the measurement of cloud altitudes, aged eighty-eight.

Mr. A. Eidinow, of the National Institute for Medical Research, London, known for his work on the principles of ultra-violet ray therapy, on March 22.

Dr. James H. Kimball, since 1936 principal meteorologist of the U.S. Weather Bureau, on December 21, aged sixty-nine.

NEWS and VIEWS

Prof. W. H. Pearsall, F.R.S.

PROF. W. H. PEARSALL, who has held the chair of botany at the University of Sheffield since 1938, has accepted an invitation from the University of London to become Quain professor of botany at University College, London, from October next. Prof. Pearsall is a graduate of the University of Manchester. After serving in France in the War of 1914–18, he became lecturer and afterwards reader in botany at the University of Leeds, where he founded his reputation in research and teaching. His researches cover a wide range in the fields of ecology and plant physiology, but it is for his contributions to plant ecology that he is best known. He was the first in Great Britain to make a comprehensive study of the vegetation of lakes and to work out the essential relationship which exists between the type of aquatic community and the nature of the substratum. This led to the recognition and the elucidation of the relationship which also exists between the distribution and periodicity of the plankton algæ and the character of the dissolved substances present in lake waters. His work on these problems and others connected with the plant communities of woodland, moorland and bog considered in relation to soil chemistry has given inspiration to many plant ecologists. His contributions to plant physiology include numerous papers on growth and nitrogen metabolism.

Prof. Pearsall acted as joint secretary of the Society for Experimental Biology for many years, he became editor of the *Journal of Ecology* in 1938 and was elected a fellow of the Royal Society in 1940. He played a leading part in the establishment and progress of the Freshwater Biological Association of the British Empire, and for many years conducted postgraduate vacation courses at the Association's laboratories at Wray Castle, Windermere.

New British Agricultural Attaché at Washington and Agricultural Adviser at Ottawa

PROF. JAMES A. SCOTT WATSON, Sibthorpian professor of rural economy in the University of London, who for the past two years has been agricultural attaché on the staff of His Majesty's Ambassador to the United States of America and agricultural adviser to the High Commissioner for the United Kingdom in Canada, will shortly be returning to Great Britain and he will be succeeded by Prof. Robert Rae, professor of agriculture in the University of Reading. Prof. Rae was trained at the University of Edinburgh and the Edinburgh and East of Scotland College of Agriculture. After a short period as lecturer in agriculture at the East Anglian Institute of Agriculture at Chelmsford, in 1921 he became vice-principal of the Hertfordshire Institute of Agriculture, St. Albans. In 1925, he left St. Albans for Northern Ireland, where he was appointed professor of crop and animal husbandry at the Queen's University, Belfast, director of the Agricultural Research Institute of Northern Ireland and head of the Crop and Animal Husbandry Research Division of the Ministry of Agriculture for Northern Ireland. In 1933 he became professor of agriculture at the University of Reading.

Prof. Rae has had wide experience of agriculture under both peace and war conditions. He is a member of various committees of the Berkshire War Agricultural Executive Committee, and serves on the board of the National Institute for Research in Dairying and on the Committee of the Reading Artificial Insemination Centre. He is also a member of the executive committee of the Land Settlement Association. Prof. Rae will be no stranger to the United States, for in 1943 he visited America at the invitation of the United States Department of Agriculture. He travelled widely, visiting agricultural colleges and farming conferences and speaking on British agriculture in war-time, and giving particular attention to the American system of agricultural education.

Dr. G. O. Curme: Willard Gibbs Medallist

DR. GEORGE O. CURME, JUN., vice-president and director of research of the Carbide and Carbon Chemicals Corporation, New York, has been awarded the Willard Gibbs Medal of the Chicago Section of the American Chemical Society for 1944. The award, one of the highest distinctions in American chemistry, is bestowed annually in recognition of eminent work in, and original contributions to, pure or applied chemistry. Dr. Curme has been responsible for the development of the Carbide and Carbon Chemicals Corporation and for its outstanding advances in the field of aliphatic chemistry. Dr. Curme was born in Mount Vernon, Iowa, on September 24, 1888. He received the B.S. degree from Northwestern University in 1909 and the Ph.D. from the University of Chicago in 1913. He continued his graduate studies in Berlin, and during 1914–20 he was a fellow at the Mellon Institute for Industrial Research, Pittsburgh. He became chief chemist of the Carbide and Carbon Chemicals Corporation in 1920, and since 1927 has been vice-president and director of research. He received the Chandler Medal in 1933, the Perkin Medal in 1935, and the Elliott Cresson Medal in 1936.

Prof. E. Pavlovsky

PROF. EVGENI PAVLOVSKY, of the Academy of Sciences of the U.S.S.R. and lieutenant-general of the Soviet Medical Service, has been awarded the Order of Lenin on the occasion of his sixtieth birthday, and in recognition of his scientific work in the field of parasitology. Since 1929 Prof. Pavlovsky has occupied the chair of zoology and comparative anatomy at the Military Medical Academy of the U.S.S.R., and has taken part in expeditions to Central Asia, the Caucasus, Crimea, Trans-Baikal, Iran and Iraq. Several years ago, settlers in the virgin forest districts of the Siberian Taiga caught an unknown disease affecting the tissues of the cerebrum and nervous system; mortality was 25 per cent, and survivors were incapacitated. After persistent work in the Taiga, Pavlovsky discovered the causative agent and elaborated methods of combating it. For this work he was awarded a Stalin Prize in 1939. Pavlovsky has also carried out extensive work in combating typhoid and malaria. He has led a number of expeditions charged with the task of improving health conditions in newly developed agricultural territory and on industrial construction sites in new areas. For many years he has headed the Department of Parasitology of the All-Union Institute of Experimental Medicine. During the War Pavlovsky has done a great deal of work on infectious diseases of the Central Asiatic Soviet Republics and neighbouring countries.

Penicillin Committee

SIR ANDREW DUNCAN, Minister of Supply, has announced that Sir Henry Dale, president of the Royal Society, has been appointed chairman of the Penicillin Committee. The Committee is constituted as follows: Mr. Arthur Mortimer, deputy director of medical supplies, Ministry of Supply (vice-chairman); Dr. V. D. Allison, Ministry of Health; Lieut.-Colonel H. J. Bensted, Army Medical Department, War Office; Prof. R. V. Christie, Medical Research Council, director of the Medical Professorial Unit at St. Bartholomew's Hospital, London; Dr. A. N. Drury, Medical Research Council, director of the Lister Institute; Prof. A. Fleming, professor of bacteriology in the University of London (St. Mary's Hospital Medical School); Prof. H. W. Florey, professor of pathology in the University of Oxford; Dr. C. R. Harington, secretary of the Medical Research Council; Prof. I. M. Heilbron, professor of organic chemistry in the Imperial College of Science and Technology and scientific adviser to the Minister of Production; Prof. R. P. Linstead, deputy director of scientific research, Ministry of Supply, professor of organic chemistry, Harvard University; Prof. H. Raistrick, professor of biochemistry in the University of London; Sir Robert Robinson, Waynflete professor of chemistry in the University of Oxford; Sir Russell Wilkinson, military medical adviser, Ministry of Supply; and representatives of firms engaged in the production of penicillin.

Intelligence and Season of Conception

IT is beyond reasonable doubt, according to Dr. J. Fraser Roberts (*Brit. Med. J.*, March 4, 1944, p. 320), that children conceived in winter are, on the average, somewhat more intelligent than those conceived in the summer; but this fact has been almost universally misinterpreted. Practically every hypothesis brought forward to explain it has depended on the assumption that it is the season of conception that influences the intelligence of the child. Some have even urged the benefits of planned winter conception (for example, Mills, C. A., *Human Biology*, 13, 378; 1941). Dr. Fraser Roberts has tackled the problem by comparing winter and summer children born to the same parents, arguing that, if the season of conception influences the intelligence of the child, the usual difference will be found in such groups; if, however, the real explanation of the observed difference is the fact that the intelligence of the parents influences the season of conception, the two groups will show no difference. A second line of inquiry was the determination of the number of sibs of comparable groups of winter and summer children. Admitting that the evidence that he has gained is not based on very large numbers, Dr. Fraser Roberts concludes that the rather greater intelligence of the child conceived in winter is not due to seasonal influences on the mother or on the developing child; but to the tendency for the more intelligent parents to conceive children rather more often in the winter, while the less intelligent people tend to conceive children rather more often in the summer.

Sunflowers as an Oil Seed Crop

IN the February issue of *Agriculture* there is an account of the progress made during the last four years on the development under English conditions of the sunflower as an oil seed crop, which was also referred to by Mr. E. F. Hurt in a lecture to the Royal Horticultural Society (NATURE, February 26, p. 248). This work, started in 1940 at the Imperial College of Science and Technology by Mr. G. E. Blackman, has since been continued by him and a research team under grants from the Ministry of Agriculture and the Agricultural Research Council. To date it has been found that only semi-dwarf varieties, capable of ripening seed in August or early September, are suitable to Great Britain, for the giant varieties, which mature in the autumn, are very prone to attack from Botrytis. Besides the selection of three varieties—'Pole Star', 'Southern Cross' and 'Mars'—the course of the investigations has demonstrated the primary importance of spacing in controlling maximal yield and the relative small part played by soil type or manuring. By close spacing, yields much in excess of the average in other sunflower producing countries have been obtained, while the seeds are not inferior in the quantity and quality of the oil and protein. In addition, methods of harvesting and threshing suitable for English conditions have been devised. In 1943, the crop was first grown on a field scale on some twenty farms and this year the developmental work is to be expanded. The outlook for sunflowers as a new crop in England appears of distinct promise.

Vacation Work Scheme of the Imperial College

THE Imperial College Union in its ninth annual report of its vacation work scheme shows an interesting record of development for the past year. Under this scheme, students of the Imperial College of Science and Technology are placed, during their vacations, in works and laboratories of industrial firms and of research institutions. During 1943, nearly 500 students registered for this purpose as compared with 180 in 1941, and 226 firms co-operated in this enterprise as against 124, so rapid has been the growth in popularity of the scheme. One of the most significant and welcome features is the extent to which firms have willingly co-operated in securing to the students entrusted to their care, the best possible and the most varied training and experience during their time at these institutions. In many cases a survey of the organization and administration is provided by lectures and tours conducted by members of the staff, in addition to the opportunity to take part in the productive processes in factory, workshop or laboratory. In this way the vacation work scheme at the Imperial College would appear to add to the theoretical studies of the students, whatever their branch of science or engineering, a valuable insight into the structure of industry, and enables them to see at first hand how wealth in the true sense is created from the organized skill and experience of all grades of workers, and how the various branches of science contribute in practice to this end.

In December 1943, the vacation work committee convened a highly successful conference of representatives from a number of the co-operating firms, at which a searching analysis was made by many speakers of various aspects of this scheme. From this it was evident how conscious were these institutions and firms of the part they have to play, jointly with the universities and technical colleges, in the creation of a highly trained body of scientific and technical workers. The scheme is under the chairmanship of Prof. H. Levy, who represents the governing body of the Imperial College; the secretary of the vacation work committee is Mr. J. Newby.

Evolution and Entropy

FOR an essay on "Evolution and Entropy" Mr. E. H. Betts has been awarded the Langhorne Orchard Prize of the Victoria Institute. The main thesis propounded is, that since in the author's opinion 'evolution' is contradicted by the law of entropy and the latter is beyond all question true, then 'evolution' is false or presumably has not taken place. The argument is put forward in a plausible manner and the essay makes interesting reading. What the author understands or means by 'evolution' is not at all clear, and sometimes he uses the word in the sense of change from simple to complex, sometimes it appears to have a moral, ethical or even religious meaning, and sometimes it is a striving towards perfection, whatever that may be. It is a relatively simple matter to endorse any of these points of view by quotations from some author or other, and then reduce to an absurdity or contradiction deductions that can be made from such quotations. Stress is laid on the difficulty of giving a logical statement of the derivation of living from non-living matter, but it seems equally clear that the law of entropy postulates the existence of matter capable of physical measurement but throws no light upon the origin of the matter itself. The ordinary mind has difficulty in imagining, let alone comprehending, that originally there was nothing, and then suddenly there was something ; or the other alternative, that matter has always existed.

Mr. Betts suggests that in Nature and history the direction of progress is from complex to simple ; presumably the organization of our society to-day is more simple than that of the ancient Britons. No biologist familiar with fossil faunas and floras would agree that this is true of the geological records of animals and plants. But perhaps all is well, for the author himself uses the sentence "Evolution itself thus rapidly evolved", and so employs a word which is extremely convenient to express the general idea that, in non-living as in living things, with the passage of time, a change or progression, so long as this is not intended to mean a movement limited to one direction, is, in fact, observable.

Differential Fertility in Canada

CANADA with its many wide spaces and farm lands has tended in the last few years to become more industrialized. It contains a large population of emigrants or the immediate descendants of emigrants from parts of Europe where tradition has influenced the reproductive tendencies of the people. For the future of Canada, which is under-populated, it is of some concern to understand the fertility of different groups of the population in order to supply information for policy-framing. Enid Charles (*Canad. J. Econ. and Pol. Sci.*, **9**, 175 ; 1943) presents an analysis of the differential fertility as seen in the 1931 census. The highest fertility is seen in Quebec and New Brunswick, the lowest in Ontario and British Columbia. There is high fertility among farmers, fishermen and food operatives, and low fertility among textile operatives, loggers, personal service workers, salesmen, owners and managers of manufacturing concerns. The late marriage of office workers and loggers could account for their low replacement birth-rate, while the small size of families of owners and managers accounts for the low fertility of these classes. Provincial differences contribute equally with occupational differences to fertility differences, while origin and religion of the individual are contributing causes. It is important to note that British Columbia, with a comparatively small population, is in reality urban in type—it has a high plane of living, a large majority of Protestants. The fertility is low. In a developing country like Canada, it should be possible to frame the policy and development of the country to enc urage higher birth-rates in those sections of the community which are reduced, but it would seem that the Canadian population may tend to repeat the faults of several European countries unless a check is made by constructional legislation.

Nature of the Viruses

PROF. B. F. OSORIO TAFALL, National School of Biological Sciences, I. P. N., Mexico, has an article with the title "Naturaleza De Los Virus", in *Ciencia* of August 1943, which gives a very useful survey of the work done on viruses. While there is nothing added to our knowledge of the subject by this contribution, it provides an excellent historical review, and as it is written in a popular form, it will prove acceptable to many readers. Among the methods of studying viruses are ultra filters, colour tests (used to investigate psittacosis), photomicrography by ultra-violet light, the electron microscope, etc. New laboratory methods for diagnosing certain diseases caused by a virus which attacks both man and animals have been developed recently. Thus, Hertz described in 1942 how the allantois of the embryo of a chicken, when inoculated with the virus *A* and *B* of influenza, possesses the power of agglutinating the hæmatin, and this provides a simple test for detecting the virus of influenza in the throat and for determining the antibodies existing in the serum of the patient. The subject will be continued in a later issue of *Ciencia*.

The Colômbian Hypericum

AN article under the title "Algunos Chites Nuevos Colombianos" appearing in *Ciencia* of August 1943 (published in Mexico) deals with the Colombian *chite*, a plant belonging to the genus Hypericum. This genus comprises about three hundred known species which are distributed in the subtropical regions, being scarce in the temperate zones. Colombia has many forms of the plant and up to the present twenty-five species have been found in the country. The author of the article, Jose Cuatrecasas, Escuela Superior de Agricultura Tropical, Cali, Colombia, acknowledges his indebtedness to Dr. Prittier, through whose kindness he has been enabled to study *H. caracasanum*. As a result of his investigations a number of previous identifications have been altered, and changes made regarding certain species and new varieties. Short descriptions are given of *H. ruscoides*, *H. magniflorum*, *H. stenoclados*, *H. tamanum* and *H. lancioides*.

Earthquakes Registered in New Zealand and Spain

DURING November 1943, seven strong earthquakes were registered by the seismographs at the New Zealand observatories. These were on November 2, 4, 6 (two), 13, 26 and 28. The shock of November 26, with an epicentral distance from Wellington of about 83°, had a focal depth estimated between 130 km. and 140 km. In addition, nineteen earthquakes were felt in some part of New Zealand. The strongest three of these had intensity VI and were felt (1) on November 5 from Greymouth to Arthur's Pass, (2) on

November 5 later in the day in the southern parts of North Island, and (3) on November 24 in the south-west parts of South Island.

In Spain during the same month, twenty-five earthquakes were registered by the seismographs at the Geophysical Observatory at Toledo. The earthquake of November 11, registered at 22h. 57m. 51s. G.M.T., had an estimated epicentral distance from Toledo of 370 km. and a focal depth of 25 km. Its epicentre is likely to have been in the neighbourhood of lat. 37·4° N., long. 1·7° W., which is just west of the town of Aquilas on the Mediterranean coast of Spain. The earthquake was felt at Granada with intensity V.

Study of Physical Medicine

According to the *Journal of the American Medical Association* of December 25, the first centre for the scientific study and development of physical medicine as a branch of medical practice has been established by the National Foundation for Infantile Paralysis in the Graduate School of Medicine of the University of Pennsylvania. The centre will include a department for development of physical medicine as a scientific part of the practice of medicine, a training centre for medical leaders and teachers in this branch of medicine, and a school for training technical workers. The departments of anatomy, physiology pathology and other basic sciences of the University of Pennsylvania will co-operate in this proposed programme.

The Chronica Botanica Co.

The Chronica Botanica Co., of Waltham, Mass., has issued a special edition of Dr. C. A. Browne's "Thomas Jefferson and the Scientific Trends of his Time" (an advance reprint from *Chronica Botanica*, 8) on the occasion of the tenth anniversary of its establishment. The Chronica Botanica Co. was founded in Leyden, the Netherlands, in September 1933, and was transferred to the United States early in 1940. An old, interesting, symbolic engraving, reproduced on an insert with the commemorative booklet, recalls the successful transfer of the firm's entire stock and its unique collection of source material in the history of botany and horticulture, just a few months before the invasion of the Low Countries. The firm, which is directed by Dr. Frans Verdoorn, publishes *Chronica Botanica*, "A New Series of Plant Science Books" and *Annales Cryptogamici et Phytopathologici* (formerly *Annales Bryologici*). Special projects in the course of preparation include: "Plants and Plant Science in Latin America" and the "Index Botanicorum".

American Academy of Arts and Sciences Grants

Income from the Permanent Science Fund of the American Academy of Arts and Sciences is used to support scientific research in the fields of mathematics, physics, chemistry, astronomy, geology, geography, zoology, botany, anthropology, psychology, sociology and economics, history and philology, engineering, medicine, surgery, agriculture, manufacture and commerce, education, or any other science of any nature or description. Equipment purchased outright through a grant from the Fund is subject to reassignment by the committee of award, upon termination of research in the particular field of endeavour in support of which a grant is made. Grants are not made for the financial support of work the results of which comprise partial fulfilment of requirements for an academic degree. It is a policy of the committee of award not to approve requests for general permanent equipment for institutions. Applications for grants-in-aid should be made on forms to be obtained from the chairman of the committee, and will be considered on June 1 and October 1. Communications should be addressed to John W. M. Bunker (chairman), Permanent Science Fund Committee, Massachusetts Institute of Technology, Cambridge 39, Massachusetts.

Announcements

The Executive Council of the Imperial Agricultural Bureaux has elected Mr. G. H. Creasy (Colonial Empire) as chairman in succession to Mr. Shamaldhari Lall (India). Lieut.-Colonel J. G. Robertson, representative on the Council of the Dominion of Canada, was elected vice-chairman.

The Colonial Office announces that Dr. E. E. Williams, of Trinidad, has been appointed secretary of the Agricultural Committee of the Caribbean Research Council. Dr. Williams, who has been assistant professor of social and political science at Howard University, Washington, has made a special study of economic problems in the British West Indies. He was born in 1911, and graduated at the University of Oxford.

The Secretary of State for the Colonies has decided, after consultation with the Governors of Northern Rhodesia and Nyasaland, to appoint a joint development adviser for the two territories, and Mr. G. F. Clay, director of agriculture in Uganda, has been appointed to the post. Mr. Clay has recently served as director of supplies for Uganda and director of native production for East Africa.

Many have been wondering how the gypsies have fared during the European War. After all, less than most folk are they concerned with the social and economic causes which have given rise to the present conflagration. The present issue of the *Journal of the Gypsy Lore Society* (**23**, pts. 1–2) contains the life and travels of Peter Lazarovič the Rudar, a vivid account of the story of an old gypsy who has had a chequered existence. There is also an interesting study of Esther Young, an English gypsy witch.

The annual report of the Board of Regents of the Smithsonian Institution for the year ended June 30, 1941, which has already been noted in Nature (**149**, 326; 1942), has now been issued as a bound volume (Washington, D.C.: Gov. Printing Office. 2 dollars) containing in a general appendix the customary miscellaneous selection of papers, some of them original, covering a wide range of scientific investigation and discussion. This appendix runs to some 450 pages. Among the papers not previously published elsewhere are those by E. P. Walker on "Care of Captive Animals"; F. C. Craighead on "The Influence of Insects on the Development of Forest Production and Forest Management", and F. C. Chase on "Useful Algæ". A number of others, such as those of H. C. Hottel on "Artificial Converters of Solar Energy"; J. W. Lasley, jun., on "Mathematics and the Sciences"; H. E. Munsell on "Vitamins and their Occurrence in Foods"; and W. N. Fenton on "Contacts between Iroquois Herbalism and Colonial Medicine", are now made more accessible to scientific workers.

Ascorbic Acid and Hip Fertility in Rosa Species

FOR the past few years we have been studying the genetical and other problems presented by a rose population growing on a pit heap in Co. Durham. Only two species, *Rosa mollis* var. *typica* and *R. dumetorum* var. *ramealis*, are involved; but, in addition, there is a unique hybrid between the two which, as it possesses a chromosome complement of thirty-five, has the parentage *dumetorum* ♀ × *mollis* ♂.

Among the points investigated were the ascorbic acid contents of the three forms. These worked out at 1,420 mgm. of ascorbic acid per 100 gm. of flesh in the case of *R. mollis*, 724 mgm. for *R. dumetorum* and 941 mgm. for *R. dumetorum* × *R. mollis*. Such results instantly raise doubts respecting the correlation which Gustafsson and Schröderheim[1] seek to establish between low hip fertility and amount of ascorbic acid.

Although the average height of the individuals composing the *R. mollis* colony is just below 1 m., and that of the *R. dumetorum* forms a little more than 1·5 m., owing to the influence of heterosis, our hybrid attains a height of 4 m. and sprawls over a very considerable area. Nevertheless, its fertility is extremely low; of the four thousand flowers it was estimated to carry in June 1942, the bulk fell at once when the fruit began to develop in July. In the end, only twenty-eight ripe hips were displayed in September and October. Of these, nine contained no mature achenes, eight had one each, eight had two, two had three and one had six—an average of 1·28 per hip. If these results are compared with an average of thirty-one achenes per hip observed in the *R. mollis* colony, and twenty-nine per fruit in the *R. dumetorum* group, a full appreciation of the general sterility of the hybrid and of its low hip fertility will be gained. Further, when the ascorbic acid contents of the three forms are set alongside these figures, it will be obvious that our findings afford no confirmation of Gustafsson and Schröderheim's attempted negative correlation between hip fertility and ascorbic acid content.

In our opinion the results are simply a matter of heredity. Nor do we consider that Table 1, as put forward by Gustafsson and Schröderheim, supplies weighty evidence opposed to that view. In the first place, it should be emphasized that, owing to the marked difference in chromosome complements in the male and female gametes in the Canine roses, reciprocal hybrids in which they are concerned are not only quite dissimilar, but also are capable of manifesting certain characters in an exaggerated fashion. Moreover, it should be noted that Gustafsson and Schröderheim state definitely that their hybrid between "*R. canina*" and *R. rubiginosa* showing the less ascorbic acid value ripens later—a fact known to be correlated, independently of any hip sterility or fertility, with a lower content of vitamin C.

Again, we should like to urge that "Cases 1 and 2", considered by Gustafsson and Schröderheim and summarized in Table 2, are vitiated as evidence by facts not immediately apparent to British workers. Their "*Rosa canina*" includes four series regarded as species by British rhodologists: these are *R. canina*, *R. dumetorum*, *R. dumalis* (*Afzeliana*) and *R. coriifolia*, the former pair characterized by biotypes with low ascorbic acid values, and the latter pair by biotypes containing relatively high amounts. We cannot conceive how material so genetically heterogeneous, and so diverse in its ascorbic acid heredity, can be assembled promiscuously for mathematical treatment in such a way as to yield figures of real significance.

Lastly, it is asserted that, for a full ripening of a rose receptacle, only one or two fruits are required, which seems to imply that at least one must be present. In our experience, such development will occur in the absence of seeds. At present, we have under observation an example of the hybrid *R. Sherardi* ♀ × *R. spinosissima* ♂, which flowers freely but fruits sparingly; on the average, no fewer than 55 per cent of its hips, usually well developed, contain no mature achenes, and such cases could be extended materially.

J. W. HESLOP HARRISON.
G. A. D. JACKSON.

King's College,
Newcastle upon Tyne, 2.
Feb. 21.

[1] NATURE, 153, 196 (1944).

IN the course of an investigation of rose hips as a source of vitamin C, undertaken with Dr. Magnus Pyke[1], no marked correlation was observed between the ascorbic acid content of the hip flesh and the percentage weight of achenes (nutlets or pips) in the hips. The publication by Gustafsson and Schröderheim[2] of their hypothesis that vitamin C content is negatively correlated with hip fertility has induced me to re-examine the earlier data together with some obtained later.

The range and the mean of both vitamin content and pip content differ from species to species. Thus, in *Rosa canina* a mean vitamin C content of 493 mgm. per 100 gm. of hip flesh and a mean pip content of 39 per cent was found, while in *R. Afzeliana* the figures were 1,121 mgm. and 36 per cent respectively. The effect of mixing data from two such species, as do Gustafsson and Schröderheim in their Case 1, would be to produce a false negative correlation between vitamin content and pip content. It is therefore important to consider the data for each species separately.

Our most extensive series of observations concerned *R. canina* and are summarized in the accompanying table. Contrary to the suggested correlation, low vitamin contents are found associated with both the highest and the lowest ranges of pip content, although the highest vitamin value, 1055, is for a sample with a relatively low pip content, 31. The mean vitamin contents are not significantly different from one another, or from the species mean, over the central ranges of pip content which include the bulk of the observations. A very low negative correlation ($r = -0{\cdot}10$) was calculated from these data, and this was not significant ($P = 0{\cdot}4$–$0{\cdot}3$). Data for other species are equally unfavourable to the hypothesis.

If the suggested negative correlation exists, one might expect differences in the vitamin content of hips from individual bushes from year to year, according to the number of achenes matured. The figures for *R. canina* and *R. rubiginosa* given by Gustafsson and Schröderheim are contrary to this theory. Our own observations of this kind are

Range of ascorbic acid and pip contents in hips of *Rosa canina*

Weight of pips (per cent)	No. of observations	Mean vitamin C (mgm./100 gm.)	Range of vitamin C (mgm./100 gm.)
20–24	1	187	187
25–29	2	275	100–450
30–34	13	546	205–1055
35–39	28	501	115–850
40–44	23	508	164–1010
45–49	8	509	370–735
50–54	2	498	385–610
55–59	2	172	120–224
Total	79		

Species means Vitamin C content, 493 Percentage of pips, 39.

limited but generally unfavourable. Thus hips of a bush of *R. canina* var. *dumalis* assayed in 1941 had 44 per cent pips and 164 mgm./100 gm. vitamin C; but in 1942, 29 per cent pips and only 100 mgm./100 gm. Corresponding figures for a bush of *R. mollis* were 1941 : 24, 1,490 ; 1942 : 15, 1,653 ; 1943 : 23, 1,650; and for a bush of *R. dumetorum*, 1941 : 51, 920 ; 1942 : 32, 935 ; 1943 : 33, 960. More numerous data published earlier by Schröderheim[3] on *R. pendulina* (Tables 9–12) and *R. rugosa* (Tables 33–34) appear to be no more conclusive.

It is noteworthy that of the three 'cases' cited by Gustafsson and Schröderheim, the correlation is lowest and least significant for the single species *R. rubiginosa*. The correlation is a little higher and significant for the mixture (Case 1) consisting mainly of *R. canina* and *R. Afzeliana*, and the only high correlation is for a heterogeneous mixture (Case 2). Probably this progression is due to an increased mingling of species having high vitamin and low pip content with others possessing low vitamin and high pip content. Among British roses the specific differences tend in these directions and appear to be due to hereditary differences in vitamin production coupled with differences in the proportions of the receptacle, and are independent of fertility. The diversity of vitamin content and fertility between the reciprocal hybrids of *R. canina* and *R. rubiginosa*, observed by Gustafsson and Schröderheim, can be regarded as another example of a kind of variation not uncommon among hybrids and genetical in origin.

Preparation of Retinene *in Vitro*

Retinene, obtained by Wald from dark-adapted retinas, is defined as the chromogen responsible for a maximum at 664 mμ in the absorption spectrum of the blue solution obtained by mixing retinal extracts with antimony trichloride in chloroform. Such extracts show (in chloroform) an ultra-violet absorption band with $\lambda_{max.}$385 mμ. It has recently been suggested[1] that the chromogen is vitamin A aldehyde, and that it can be obtained by direct oxidation of vitamin A alcohol.

The following procedure yields small quantities of retinene in a state approaching purity. 2 gm. of distilled vitamin A alcohol ($E^{1\%}_{1cm.}$ 325 mμ 800, *c.* 46 per cent vitamin A) is dissolved in 40°–60° petrol ether (50 c.c.) and the solution poured into 5 per cent sulphuric acid (400 c.c.) at 25° C. *N*/10 potassium permanganate (600 c.c.) at 25° C. is then run in rapidly with vigorous shaking for a few minutes. The mixture is allowed to settle in a separating funnel and the aqueous layer discarded. The petrol ether layer is washed twice with water and dried over sodium sulphate. It is then poured on to a column of alumina (Brockmann) and the chromatogram developed with petrol ether. The solute is gradually washed through the column and the fractions are tested separately (1 or 2 drops with 4 c.c. antimony trichloride reagent). If each successive 10 c.c. portion of eluate is regarded as a 'fraction', the results can be summarized as in the accompanying table.

Fractions containing the 664 mμ chromogen only show

$$E^{1\%}_{1cm} \quad \begin{array}{ll} 664\ m\mu & >3200 \\ 361\ m\mu & 1420\ (petrol) \\ 385\ m\mu & 1570\ (chloroform) \end{array}$$

while the best fractions for the 560 mμ chromogen show

$$E^{1\%}_{1cm.} \quad 560\ m\mu/355\ m\mu \;=\; 2:1.$$

For both substances, the molecular extinction coefficient for the ultra-violet maximum approaches that of vitamin A. The 664 mμ chromogen is undoubtedly retinene. It is by no means an unstable substance. In cyclohexane, the ultra-violet maximum falls near 368 mμ and in petrol nearer 361 mμ. The 560 mμ chromogen (the nature of which cannot yet be discussed) is also a stable substance exhibiting a similar displacement of the ultra-violet maximum from 355 mμ in chloroform to 342 mμ in petrol. Hunter and Hawkins[2], in recording the preparation of vitamin A aldehyde by the Oppenauer method, give $\lambda_{max.}$657 mμ in the colour test and two maxima (368 and 350 mμ) for the ultra-violet absorption in cyclohexane. Wald at first gave 655 mμ for the colour test maximum, but later corrected it to 664 mμ. His ultra-violet maximum at 385 mμ refers only to chloroform solutions. The large solvent displacement, 368–385 mμ, which we have observed reconciles the data and makes it clear that retinene and vitamin A aldehyde are spectroscopically indistinguishable. We have not so far found the 664 mμ and 560 mμ chromogens to be

Fractions	Approx. conc. (per cent)	$\lambda_{max.}$ in $SbCl_3$ colour test (mμ)					$\lambda_{max.}$ ultra-violet absorp. in chloroform; in petrol (mμ)				
		620	610, 583	664	560	490	325; 325	355; 342	385; 361	332; 321	300; 287
1–10		+					+				
11–13					+	++		+			++
24–26					++			++			
27–41	0·06			+	+++			+++	+		
42–50	0·02			++	+			+	++		
51–57	0·018			+++					+++		
58–66	0·025			+					+		
67–70	0·045		+							+	+

interconvertible, and the best fractions of the former show one ultra-violet maximum only.

The elegance and accuracy of Wald's work on retinal extracts makes us hesitate to suggest that the term *retinene* is inappropriate. Unfortunately, it suggests a retinal carotenoid. *Axerophthal*, following Karrer's terminology, is not very happy in this context. Perhaps *retinaldehyde* is more appropriate than retin*al*.

A fuller account of this work will be published elsewhere. We express our thanks to the Medical Research Council for financial assistance.

Molecular Weight of Egg Albumin

THE molecular weight of egg albumin quoted in all but the most recent literature is 35,000–36,000, a value based on the early osmotic pressure measurements of Sørensen[1], the ultracentrifuge measurements of Svedberg and Nicols[2], Nicols[3], and Sjögren and Svedberg[4], as well as the diffusion data of McBain[5]. More recently, however, there has been general agreement that this value is too low; the sedimentation constant and diffusion data quoted by Svedberg and Pedersen[6], for example, as well as the osmotic pressure data summarized in Table 1, indicating a value of 43,000–46,000.

TABLE 1.

Author	Solvent used	Result
Sørensen	Water	34,000[1]
Adair (recalculated Sørensen's data)	Ammonium sulphate	43,000[7]
Marrack and Hewitt	Sodium acetate and sodium chloride	43,000[8]
Taylor, Adair and Adair	Sodium acetate	46,000[9]
Bull	Sodium acetate	45,160[10]

I have had occasion, while rehearsing the procedure to be applied to certain other proteins, to make osmotic pressure measurements with solutions of egg albumin. This protein was prepared by Prof. R. K. Cannan using the method of Kekwick and Cannan[11], and the amount in solution was estimated by the micro-Kjeldahl procedure and nitrogen figures of Chibnall *et al.*[12]. McIlwain's phosphate-citric acid buffer at pH 4·65 was used as solvent.

The osmometer used was of the type described by Adair[13], but the collodion membranes contained about 3 c.c. instead of 20 c.c. of protein solution. Pressures were calculated from the height of the column of solution of known density, corrected for the rise due to capillarity.

TABLE 2.

C_p	Pressure	Molecular weight
1·00	3·92	43,400
1·86	6·71	47,200
4·00	14·4	47,300
4·23	16·7	43,100
5·84	21·1	47,200
5·95	22·0	46,000
6·26	22·2	48,100
6·88	26·1	44,900
8·30	30·6	46,200
8·84	32·5	46,300
	Average	45,970

The computed values for the molecular weight are given in Table 2, where the pressures are recorded in millimetres of mercury at 0° C. It was found that over the range investigated the osmotic pressure was directly proportional to the protein concentration C_p, expressed in gm. per 100 c.c. solvent. The calculated results for the molecular weight, which are in agreement with those recorded in Table 1, though obtained under different conditions, show that the value is almost certainly 45,000 ± 2,000.

Number of Configurations of Molecules occupying Several Sites

IN a recent communication[1], I gave a formula for $g(N_i)$ the total number of configurations of a mixture of molecules of several types, N_i denoting the number of type i. I have meanwhile obtained the more general formula for $g(N_i,X_{ij})$, the number of configurations of the molecules in which the number of pairs of sites occupied in alternate ways is specified.

Let the number of sites which are neighbours of one site be z; let each molecule of type i occupy r_i sites; let the number of sites which are neighbours of a molecule of type i be q_iz. The r_i's and q_i's are related by $z(r_i - q_i) = 2(r_i - 1)$. Let the number of alternative configurations of a molecule of type i be ρ_i when a site has been chosen for one of its elements. Let the number of pairs of neighbouring sites, one occupied by a molecule of type i the other by a molecule of different type j, be denoted by zX_{ij}.

The number $g(N_i, X_{ij})$ of distinguishable configurations of given N_i and X_{ij} is given by

$$\log g(N_i,X_{ij}) = \Sigma_i N_i \log \rho_i - \Sigma_i \log N_i\,! + z\Sigma_i \log (q_iN_i)\,! - (\tfrac{1}{2}z - 1) \log (\Sigma_i r_i N_i)\,! - \tfrac{1}{2}z\, \Sigma_i \log (q_iN_i - \Sigma'_k X_{ik})\,! - z\Sigma'_{ij} \log X_{ij}\,!,$$

where Σ' denotes summation over all types except i. This includes as special case a formula due to Chang[2] for a mixture of two types of molecule, of which one type occupies two sites, the other a single site.

The above formula can be used to derive the thermodynamic properties of mixtures with non-zero energies of mixing, whereas my previous formula was sufficient for mixtures with zero energies of mixing. In particular, I find that T_c, the temperature of critical mixing of a binary mixture of molecules A and B, is related to w, the intermolecular energy per pair of sites one occupied by part of an A the other by part of a B molecule, by the formula

$$e^{2w/kT_c} = \tfrac{1}{2}\{1 + ab + \sqrt{(a^2-1)(b^2-1)}\},$$

where $a = zq_A/(zq_A - 2)$ and $b = zq_B/(zq_B - 2)$.

Full details are being published elsewhere. Some of the formulæ for the case of a binary mixture in which the molecules of one type occupy single sites have already been given by Orr[3].

A Modification to the Cryoscopic Equation

IT is known that the molecular weights of pure solutes as calculated by the cryoscopic method are not found to be constant for varying dilutions, and it has been reported[1] that K_f also varies, the tendency being for the cryoscopic constant to decrease in value as the concentration increases. Meldrum, Saxer and Jones[2] studied this anomaly in the case of camphor and found that for various solutes of known molecular weights, the constant for one gram-molecule per 1,000 grams of solvent fell from 50 at low concentrations to 39·7 in solutions of molality greater than 0·2.

These observations were confirmed by us not only for camphor but also for benzene, where K_f decreased from 7·20 to 5·35 between molalities 0·075 and 1·0.

The difficulty which arises from variations in both K_f and molecular weights at different concentrations has been overcome by using a modified equation of the form:

$$\Delta t = K_f . m^b \qquad (1)$$

$$\text{or } \log \Delta t = \log K_f + b \log m \qquad (2)$$

The validity of this equation was checked by plotting $\log \Delta t$ versus $\log m$ for different solutes of known molecular weights in the cryoscopic solvents benzene and camphor respectively. For all cases studied, straight lines were obtained similar to the accompanying diagram showing the plot for naphthalene and camphor in benzene.

Applying a summation method to equation 2:

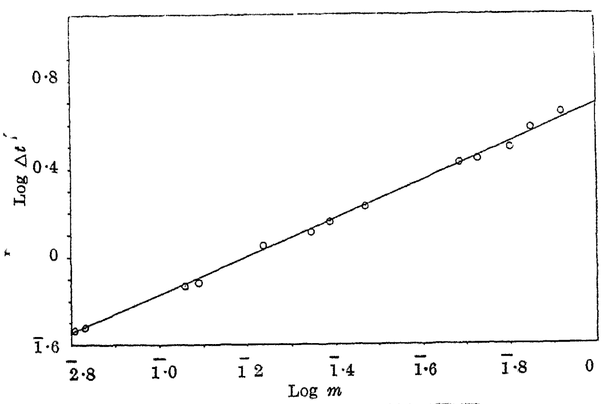
$$\Sigma \log K_f + b \Sigma \log m - \Sigma \log \Delta t = 0$$

$$\log K_f \Sigma \log m + b \Sigma \log^2 m - \Sigma \log \Delta t . \log m = 0,$$

we obtained $K_f = 5{\cdot}14$ and $b = 0{\cdot}8961$.

Hence the modified equation for pure solutes in this sample of benzene was: $\Delta t = 5{\cdot}14\ m^{0{\cdot}8961}$. For the results quoted by Meldrum *et al.* on camphor: $\Delta t = 38{\cdot}73\ m^{0{\cdot}9580}$.

K_f is found by this method to vary for different samples of the cryoscopic solvent. Thus for a different stock of benzene, $K_f = 5{\cdot}229$, whereas b, although constant for all pure solutes in a given sample of solvent, is extremely sensitive to impurities. It should be pointed out that cases may be found in which the value of b is unity and the modified equation consequently becomes identical with the classical.



NAPHTHALENE AND CAMPHOR IN BENZENE.

The accompanying table gives the molecular weights of tetralin in benzene (*a*) using the classical equation, $\Delta t = K_f m$; (*b*) using the modified equation $\Delta t = K_f m^b$.

Concentration (per cent by weight)	Depression (Δt ° C.)	Molecular weight calculated on $\Delta t = 5{\cdot}229\ m$ (classical)	Molecular weight calculated on $\Delta t = 5{\cdot}229\ m^{0{\cdot}9394}$ (modified)
0·68	0·321	111·6	133 2
1·98	0·876	118·0	132·4
3·98	1·636	127·1	137·0
7·94	3·165	131·2	135·5
11·13	4·316	134 9	136 6

It is seen that by applying the classical equation the calculated molecular weight increases and approaches a value in the region of 132–136. Application of the modified equation, however, produces a set of reasonably consistent values, the mean of which is 136·1.

No attempt is made here to explain the anomaly of K_f at different concentrations, but it is suspected that a more rigid application of thermodynamic theory, on which the classical equation is based, is necessary. For the present, the above equation is proposed as one which gives consistent results at all concentrations below 1·0 molality.

Dissociation Energy of Nitrogen

VAN DER ZIEL[1] has observed weak predissociation in the First Positive system of N_2 for bands with v' greater than 11. The predissociation was reported to be of the type which increases in strength with the rotational quantum number J, and both Λ doubling components of the $B^3\Pi_g$ state are affected. Van der Ziel therefore concluded, apparently with good reason, that the state causing the predissociation was of type Δ. This led to the conclusion that a dissociation limit, the products of which were capable of producing a Δ state, must lie below the energy of the predissociation. Combining this information with the known predissociation limit for the $C^3\Pi_u$ state at 12·145 e.v., this gave a value of 7·383 e.v. for the dissociation energy of nitrogen, a value which has been generally accepted.

Gaydon and Penney[2] have pointed out that if this value is correct, then the rule that potential energy curves of molecular states of the same species may not cross must be violated. They suggested that the dissociation energy was probably about 9 e.v. This is now supported by the discovery that Van der Ziel's interpretation of his predissociation is not a unique solution.

The selection rules for predissociations or perturbations are usually quoted as: (1) Λ, the quantum number of the resultant electronic (orbital) angular momentum about the internuclear axis, may change by ± 1 or 0. In the former case the strength of the predissociation increases with J; in the latter case it is independent of J. (2) The $+\ -$ symmetry is unchanged, that is, $+ \rightarrow +$, $- \rightarrow -$, $+ \nrightarrow -$. For homonuclear molecules the $g\ u$ symmetry is unchanged, that is, $g \rightarrow g$, $u \rightarrow u$, $g \nrightarrow u$. (3) For strong predissociation the spin, S, must not change, but weak predissociation may occur for $\Delta S = \pm 1$. (4) The rotational quantum number remains unchanged, that is, $\Delta J = 0$.

Now for predissociation of a $^1\Pi$ state by $^1\Sigma$, it follows from the $+ \nrightarrow -$ rule that only one of the two components (due to Λ doubling) of the $^1\Pi$ state will be affected. This also appears, experimentally, to be the case for the predissociation of a $^2\Pi$ state, which is in Hund's case b, by a $^2\Sigma$ state, as, for example, in the spectrum[3] of MgH. In this case, however, each J value occurs twice for the $^2\Sigma$ state, once with $+$ symmetry and once with $-$ symmetry, so that with the selection rules as listed above there appears no obvious reason why both Λ components of the $^2\Pi$ state should not be affected. To account for the observed predissociation of one component only, it appears necessary to assume the further restriction $\Delta K = 0$. While not explicitly stated, this rule appears to have been tacitly assumed, and in case b where the rotational energy is determined chiefly by the quantum number K, this seems reasonable.

For nitrogen, however, the $B^3\Pi_g$ state approximates to Hund's case a. In this case the rotational energy is determined by J, and K is no longer a true quantum number. Thus the rule $\Delta J = 0$ may be expected to hold, but not $\Delta K = 0$.

Now the lowest dissociation products for nitrogen are $N(^4S) + N(^4S)$, and these products can, on the Wigner-Witmer correlation rules, lead to a $^5\Sigma_g^+$ state. In this state each rotational level will be split, by spin, into five components, so that each J value occurs five times, thrice with one symmetry (say $+$) and twice with the other symmetry (say $-$). Thus, assuming that for the predissociation of the case a $^3\Pi_g$ state, only the selection rule $\Delta J = 0$ holds, both Λ components of the $B^3\Pi_g$ state may be affected. Thus it appears that Van der Ziel's explanation of the predissociation is not the only one possible, but that it might equally well result from a repulsive $^5\Sigma_g^+$ state arising from normal dissociation products. This latter explanation is preferable, because, by using the higher value for the dissociation energy to which it leads, the non-crossing rule for the potential energy curves can be maintained.

It thus appears that the dissociation energy of nitrogen is 9·764 e.v.

The dissociation energy of nitric oxide is linked thermochemically with that for nitrogen, and the new value for $D(N_2)$ leads to $D(NO) = 6{\cdot}49$ e.v. instead of 5·29 e.v.

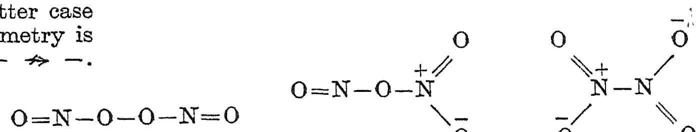
Structure of the Nitrogen Peroxide Molecule

HITHERTO three structures for the nitrogen peroxide (N_2O_4) molecule have received support:



(i) (ii) 2 resonance states (iii) 4 resonance states

Study of the electron-diffraction pattern of nitrogen peroxide gives no conclusive evidence as to the structure[1]. The X-ray diffraction pattern of the powdered solid suggests that the molecule is symmetrical, but gives insufficient parameters to fix the relations of the atoms[2].

Structures i and ii are *a priori* chemically reasonable. However, the vibrational (infra-red and Raman) spectra of N_2O_4 indicate that the molecule is highly symmetrical and non-linear[3,4]. The value of the entropy[5] also supports a more symmetrical structure.

Structure iii predicts satisfactorily the vibrational frequencies of N_2O_4, if it is supposed that the N—N link has the abnormally low force constant $1{\cdot}5 \times 10^5$ dynes/cm. On the basis of this model, the spectroscopic data give a value of the entropy in good agreement with the thermodynamically measured value, but only if it is assumed that there is no free relative rotation of the ends of the molecule about the central link[5]. This structure violates Pauling's adjacent charge rule[6], for which there is much empirical evidence; and it is difficult to reconcile the weakness of the N—N link with its torsional rigidity.

A fourth structure

(iv)  (planar: 2 resonance states)

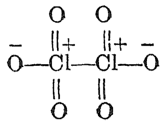
is here proposed. This model has the same symmetry as the planar form of iii, and gives precisely the same numbers of fundamental frequencies in both the Raman and infra-red spectra. Qualitatively, therefore, it gives as good a fit with observation as the planar model iii, which has been shown to account satisfactorily for the vibrational spectra[3], though Harris and King[7] consider that some of the molecules may have the twisted form. The observed fundamentals can be simply interpreted in terms of the valence-force model iv: in particular, the low Raman frequency at 283 cm.$^{-1}$, previously interpreted as the oscillation of a very weak N—N link, is now attributed to an angular deformation of the ring, which would be expected to involve a small energy change compared to that associated with the stretching of a covalent link. Moreover, there is no motion of iv corresponding to internal rotation in iii, so that there is no need to explain, as for the latter, why such a motion makes no contribution to the entropy. Detailed analysis of the vibrational spectra on the basis of iv is now in progress. Further, iv is in accordance with the adjacent charge rule.

Other compounds containing a 4-membered ring of this type are the carbonato- and sulphato-com-

plexes, and the molecule HI_3O_8. Such a ring is probably also present in chloride hexoxide (Cl_2O_6), as might be expected from the formal analogy between the pairs of compounds:

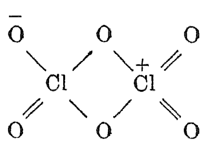
$$\begin{array}{lllll} ClO_2 & ClO_3 \rightleftharpoons Cl_2O_6 & Cl_2O_7 & Cl_2O_8 \\ NO & NO_2 \rightleftharpoons N_2O_4 & N_2O_5 & N_2O_6 \end{array}$$

As usually written:



(ethane-like model, in which each double bond has partial co-ordinate-link character)

the structure of Cl_2O_6 violates the adjacent charge rule. The alternative structure



here proposed is similar to the structure iv above for nitrogen peroxide. There are four possible resonance states, not counting those in which some or all of the double bonds are replaced by co-ordinate links. In the structure shown, the right-hand Cl atom has the same valency state as the Cl in the tetrahedral $[ClO_4^-]$ ion, and the left-hand atom is pentavalent as in the pyramidal $[ClO_3^-]$ ion. Hence the chlorine atoms are probably tetrahedral, in which case chlorine hexoxide is geometrically analogous to the dimeric aluminium halides, and to the derivatives $M_2H_2R_6$ (M = B or Ga, R = H or alkyl) of boron and gallium[8,9]. However, the vibrational spectrum of Cl_2O_6 has not been measured, and there is no other direct experimental evidence yet for either structure.

Women with Colour-Blind Relatives

AN experiment was carried out on 98 women and 104 men with 'normal' red-green vision, on 4 women and 14 men who had various degrees of red-green blindness, and on 3 men who are green-anomalous because they reject the normal Rayleigh equation by a wide margin. The experiment was along the lines of Collins's research on the Rayleigh equation with rotating disks[1], and the details of the technique and other results will be published later.

The 'normal' women subjects were all asked to give information about any colour-blind relatives so far as they were able, and some of these relatives were among the colour-blind men and women tested. Colour-weak subjects, like the colour-blind, accept a wider range of matches in the Rayleigh equation than do the most sensitive normal subjects. These differences in range were measured by an efficient psycho-physical technique, together with the usual deviations in the Rayleigh equation.

If we pick out those women who pass the Ishihara test with little or no difficulty and therefore are not colour-blind, who accept or almost accept the normal Rayleigh equation and are therefore not anomalous, but who can make *at least twice the modal range of* matches in the Rayleigh equation carried out in this research, then the accompanying table can be constructed. For this table chi-squared is about 20, calculated from the marginal totals, showing that it is extremely unlikely that such differences could have been obtained by chance. The table is strong evidence that women who are blood-relatives of colour-blind subjects, and who, accordingly, must often be potential if not actual mothers of colour-blind sons, have a decided and measurable red-green weakness much more frequently than women in general.

WOMEN WITH 'NORMAL' RED-GREEN VISION.

	Known C-B relative	No known C-B relative
Twice modal range or more	11	7
Less than twice modal range	10	70

I am indebted to Dr. Mary Collins for her advice in setting up the experiment and to Mr. Joseph F. Simpson for frequent help.

Colonial Geological Surveys

IN his article on Colonial Geological Surveys in NATURE of March 4, Mr. V. A. Eyles gave a useful résumé of recent discussions. There are, however, some further considerations to be noted. The figures he quoted from Sir Edmund Teale's paper of the results of mining operations, following upon the activities of Colonial Geological Surveys, do not include any statement of the amount and disposal of mining profits, or of the proportion of such profits set aside for the benefit of the local inhabitants as compensation for the loss of their national wealth. Thus arises the impression in some Colonial circles that Geological Surveys exist mainly for the benefit of outside mining interests—an erroneous impression which leads to friction between Geological Surveys and other Government Departments, administrative, agricultural, educational, etc., more directly engaged in promoting the welfare of the local inhabitants. Some change in Colonial policy after the War seems, therefore, desirable.

It is to be hoped that in the future the rights of ownership of their own mineral wealth by the people of the Colonies will be fully recognized, that the pre-war policy of exploitation of minerals by outside interests will become a matter of history and that the mineral resources of the people will be worked with the approval and for the benefit of the people, either by the people themselves or by the Colonial Governments on their behalf.

J. D. FALCONER.

London, W.5.

NATIONAL INSTITUTE OF ZOOLOGY AND BOTANY, ACADEMIA SINICA

THE research activities in zoology and botany conducted by the National Institute of Zoology and Botany of Academia Sinica during 1943 can be grouped into six sections, namely, ichthyology, entomology, protozoology, phanerogamic botany, algology, and cytology. The results are presented in epitome as follows:

Ichthyology

For four successive years the important edible fish, *Monopterus javanensis*, has been the main object of study. The anatomy as well as the physiology of its accessory respiratory organ, namely, the bucco-pharyngeal epithelium, its breeding habits and metamorphosis and the function of its larval organs have previously been discussed. In 1943, the whole blood vascular system was carefully worked out, and earlier accounts have required considerable modification. The integumentary serous glands of this fish, with their peculiar distribution around the pericardial region, were studied, and the hatching phenomena with which these glands are chiefly concerned were described. Particularly interesting was an investigation on the sexuality of this fish; Monopterus starts its life always as a female, undergoes sex-reversal after laying eggs, becoming eventually a male. Its growth-rate under natural condition was also studied simultaneously.

As a proof of the capability of hypertonic excretion in a purely freshwater teleost as a means of osmotic regulation, the paradise fish, *Macropodus opercularis*, was shown in 1942 to produce a crop of chloride-secreting cells in its gill lamellæ when it is acclimatized in a strong sodium chloride solution. In order to ascertain whether the secretory activity of these cells is limited to chloride alone, as their name implies, the same experiment was repeated with sodium sulphate instead of chloride; the result suggests that secretion is not limited to chloride (see NATURE, Feb. 26, p. 252).

An ichthyological survey has been made in the region covering Western Szechwan and Eastern Sikang. No less than a hundred species, including ten new ones, were collected and described. A comparative study of the much modified pectoral and pelvic girdles of the Homalopterid fishes, which are adapted with remarkable success to life in torrents, is now being carried on, in the hope of elucidating the phylogenetic relationship within the group.

Entomology

In systematic entomology, much emphasis has been laid on the white flies, Aleurodidæ, the fruit flies, Trypetidæ, and the leaf beetles, Chrysomelidæ. Investigations on the white flies of Szechwan and on the cucumber beetles of China have already been completed, and have proved of value not only to insect taxonomy as a whole, but also to the economic position of the groups studied.

Morphological investigations of insects have also been undertaken. The study of Malpighian tubes in Chrysomelidæ has helped to clear up the systematic position of the sub-family Eumolpinæ. In the study of the tibial tympanic organ of Conocephalus, attention has been directed particularly to the structure of the crista acustica and to the functional aspect of the whole organ. Comparisons of the elytral tracheation of Dermaptera with that of Protelytroptera, a Palæozoic order, were made, and the possibility of the Dermaptera being derived from Protelytroptera was taken into consideration.

Some experiments were conducted to demonstrate the effect of light on orientation of the cicada *Cryptotympana pustulata*, and also the change of position exhibited by aphids during feeding. Inquiries were likewise attempted with regard to the part played by the elytra of Coleoptera during flight, and by the jumping spiders in checking the spread of house-flies and mosquitoes. Observations on the mode of egg-laying of the aquatic bug, *Sphærodema rustica*, show that coition is immediately followed by the act of oviposition; the two acts take place alternately and continuously, both activated by the male, and not by the female as generally believed. The problem of respiratory adaptation was investigated in another water bug, Cheirochela sp. This bug, being incapable of rising to the surface of water to obtain atmospheric air, has been obliged to overcome the difficulty by the development of pubescence on the thorax and abdomen for collecting air-bubbles under water, by the modification of certain parts of the integument to permit cutaneous respiration, and, most important of all, by the specialization of the legs to function as tracheal gills.

Protozoology

In the field of protozoology, work has been confined mostly to the dinoflagellates and Infusoria. For the former, studies have been centred in the thecal morphology of dinoflagellates, especially in the plates that constitute the ventral area, which has rarely been scrutinized by previous investigators. The thecal plates of a number of species belonging to Diplopsalis and to Ornithocercus were analysed and their number and arrangement determined. All the specimens studied were collected from the Hainan region during the years 1933 and 1934.

Surveys of infusorian fauna of Pehpei and other localities of Szechwan have been made from time to time. Five new species of epizoic ciliates were described. They are found attached either to the antennæ, legs and swimmerates or to the gills of the freshwater shrimp, *Palæmon nipponensis*. Other problems now being studied are the freshwater Sarcodina of Szechwan and the peritrichous Infusoria of Pehpei.

Phanerogamic Botany

The Umbelliferæ have been the main subject of investigation among the flowering plants. Aside from a general survey of Chinese umbellifers, the species of Bupleurum and Ligusticum, known as native drug plants, were separately treated. The anatomy of seedlings of *Coriandrum sativum*, *Fœniculum vulgare*, etc., has also been investigated. The results add much to our knowledge of the development of vascular bundles of the family Umbelliferæ as a whole.

In collaboration with the Kansu Provincial Government, a forest survey is now in progress in that province. Work is proceeding on utilization, growth-rate, and fungal diseases of timber trees. Land classification, stand and composition of the existing forests, and dendrological characters, which are exceedingly important for the formulation of forest management plans, are also being examined.

Algology

The section of algology dealt largely with the systematics of freshwater algæ. About 1,500 species were collected from different localities of Kwangtung, Kwangsi and Szechwan, and, among them, 4 genera, 75 species, and 24 varieties were described as new. Asterocapsa, a new genus of Myxophyceæ, is worthy of notice as it has reproductive cells with much the same appearance and mode of development as the more advanced autospores of Chlorophyceæ. Other three new genera, Hormothece, Brachytrichiopsis and Symphyonema, representing transitional forms of certain families, are deemed to be phylogenetically important.

Since 1941, attention has also turned to the study of algal ecology. Observations on algal communities of the Kialing River have been made at regular intervals. As affected by the condition of river-bed, the velocity of water currents, and the intensity of light, the distribution of algæ in this river naturally falls into seven distinct communities, always isolated and never forming horizontal adjoining zones like those prevalent in stagnant waters. Each community consists of only a single or very few dominant species. In addition, the seasonal distribution of algæ in a freshwater pond was thoroughly studied. Temperature, sunlight and rainfall are factors influencing the periodic occurrence of the species of phytoplankton.

Cytology

In the field of cytology, investigations on the number and behaviour of meiotic chromosomes of *Brachytrupes portentorsus* and the meiotic division in *Gesonia punctiforons* have been completed. The former demonstrates the number and structure of autosomes and the behaviour of the *X*-chromosome, whereas the latter deals especially with chromonema structure and the time of its splitting. In both cases the so-called chromomeres are believed to be mere artefacts or twists in the chromatids.

TRADE AND ECONOMICS IN THE INTERNATIONAL SPHERE

THE Economic, Financial and Transit Department of the League of Nations has issued two studies in a series on international trade and commercial policy with the view of contributing to those objectives of commercial policy, "the elimination of all forms of discriminatory treatment in international commerce" and "the reduction of tariffs and other trade barriers", which have found fresh expression in the Mutual Aid Agreements. The first of these, "Quantitative Trade Controls: their Causes and Nature"*, by Prof. G. Haberler, of Harvard University, in collaboration with Mr. M. Hill, considers what were the forces which induced Governments to adopt these measures of quantitative control; what were the relative advantages and disadvantages of such restriction compared with tariffs and other measures designed to influence trade through the price mechanism; whether quantitative controls were the most suitable instrument, and why they were so generally condemned both by international conferences and by economists, the likelihood of their adoption after the present War and the policies which should then be pursued.

This study leads to the conclusion that if the trend towards economic isolation, autarky, regimentation and State control, characteristic of the nineteen-thirties in many parts of the world, were to be renewed after the War, quantitative trade controls would necessarily take an ever-greater role. A movement in this direction would not only belie the intentions of the Governments of the United Nations as expressed in the Atlantic Charter and the Lend-Lease Agreements as well as innumerable statements of national policies; it would also prevent the achievement of those basic economic and social objectives which most of them have proclaimed—greater human welfare and full employment, within the framework of a social system designed to preserve individual liberty. These ends cannot be attained without an expanding international trade. Except over short periods, we cannot have generally regimented and socialized international trade and a domestic economy based on free enterprise.

Many countries may find it necessary to maintain exchange controls for a considerable time after the War as regards capital movements. If effective machinery is established to overcome the initial difficulties of financing the essential needs of countries left after the War without adequate means of external payment, and to facilitate multilateral clearing, it should be possible to liberate commodity trade rapidly from control via the exchanges. Of the circumstances facilitating a removal of import quotas a growth in exports appears to be the commonest, and the whole history of commercial policy in the inter-war period confirms the view that the difficulties in scaling down the barriers to trade are least formidable in times of rising prosperity.

In the period considered, the most clearly discernible factor leading governments to introduce quantitative controls was currency instability accompanied by exchange dumping. A primary cause of the currency instability was the breakdown of the mechanism of international trade and settlements as a result, first of the war dislocation and second of the catastrophic fall in prices. Discrepancies in national price structures can only be overcome by changing prices in terms of domestic purchasing power, or by changing the external purchasing power of currencies by a modification of the exchange-rates. This is one reason in favour of the establishment of special machinery by means of which credit may be furnished to meet changes in the balances of accounts, by which orderly changes in currency parities may, if necessary, be carried through, by which national monetary policies may be co-ordinated and kept in line, and multilateral trade and clearing facilitated.

Such machinery requires for its effective working concerted measures against economic depressions and for the maintenance of full employment, and these elements in a possible long-range plan for the preservation of an international economic system provide a challenge to the constructive vision and the co-operative spirit of our generation. The failure to break down the system of quantitative restrictions in the 'thirties was due not so much to a lack of understanding of the technical issues at stake as to the unwillingness of certain great States to abandon their designs for political aggrandisement or the methods by which they are able to exercise pressure on others. Wise concerted economic measures are one of the bases of a durable peace; but they provide by themselves no solution of the political problem on which the success of all efforts to create a better economic world ultimately depends.

* League of Nations, II, A.5; 1943. Pp. 45. (London: George Allen and Unwin, Ltd.) 2*s*. 6*d*.

In the second study, "Trade Relations between Free-Market and Controlled Economies"*, Prof. J. Viner analyses the difficulties which in the nineteen thirties confronted countries maintaining a substantially free trading system and relying primarily on the tariff method of trade regulation; it supplements a critical appraisal of the attempts made to meet these difficulties with constructive proposals for the future. There may be, from the national point of view, a case for national resort to direct foreign trade controls under conditions of world-wide depression, of over-valued and unstable currencies, of collapse of international credit facilities, of imminent threat of war, of the prevalence of similar controls in many other countries, and of the absence of any promise of effective concerted action to obtain relief from these evils; but Prof. Viner regards these direct methods as in general injurious to world prosperity and as barriers to international economic collaboration and harmony. Their substantial elimination is a prerequisite for the attainment of a peaceful and prosperous world.

Against all three major types of direct government regulation of foreign trade—exchange controls applied to commercial transactions, import quota systems, and government monopolies of foreign trade—six charges may be made, in different degrees. They 'tie up' diplomacy closely with the detailed conduct of foreign trade and thus promote international controversy and facilitate the injection of political and military considerations into trade relations. They lend themselves more effectively than ordinary import duties to the application of monopolistic methods to foreign trade, to the economic injury of the world as a whole. They promote bilateralism in foreign trade at the cost of multilateral trade and of the suppression of profitable foreign trade. They lend themselves to discriminatory treatment of the trade of different countries for economic or political purposes. They promote or require the development of internal monopolies and the restriction of the field for private enterprise, and especially small-scale enterprise. Finally, by placing other countries not following similar practices in a position of relative disadvantage in trade-bargaining, they tend to spread these practices to other countries.

Hope for better results from future attempts to obtain reform in this field must depend in part on the attainment, through provisions for collective security, of a reasonable expectation of a peaceful world. It must also depend on reduction of the levels of ordinary import duties in high tariff countries, on the attainment of substantial stabilization of currencies, on the establishment of procedures for concerted action to deal with mass unemployment and on provision of reasonable facilities for international credit. Rapid progress in the elimination of direct controls by bilateral negotiation cannot be expected unless greater success is attained in formulating and obtaining acceptance of unambiguous, rational and easily enforceable criteria for determining the absence or presence of discrimination and of the illegitimate use of monopoly power in trade relations; and unless there emerges from the bilateral negotiations a common pattern of policy with respect to relations with countries which continue to adhere to rigorous direct controls of their foreign trade. Equally the participating countries in their bilateral negotiations must also consider not only the protection of of their own export trade from discrimination or from monopoly pressures, but also the need for refraining from pressing for, or from accepting, concessions which involve discrimination against innocent third countries.

Prof. Viner sees brighter prospects of success in an attempt to deal with the problem in a multilateral conference. Such a conference would have as objective multilateral agreement binding the participating countries to move towards the elimination of direct controls on a mutually agreed time-schedule; to define the practices which would not be permissible in their trade relations with one another; to formulate the procedures to be followed in trade relations with non-participating countries adhering to direct controls; and to participate in the establishment of an international agency, to which questions of violation of the convention, of revision of its terms, and of admission of new countries could be referred. The technical difficulties of framing and administering a multilateral agreement of this kind would be comparatively moderate if wide acceptance could be obtained for definite and unqualified outlawry of the questionable practices, at least after a transition period had elapsed. Further progress in obtaining significant agreement in this field may be impossible except as international agreement is reached in other fields of international economic relations, notably in limiting the heights of ordinary tariffs, in establishing international credit facilities for monetary stabilization and for long-term investment purposes, and for collaboration in dealing with the problem of the business cycle and of mass unemployment. Slow progress need not be fatal, provided there is early agreement on the direction in which movement shall take place, and on procedures of negotiation which will assure that the achievement of one stage of reform will lead promptly to endeavours to accomplish the next stage.

* League of Nations, II, A.4; 1943. Pp. 92. (London: George Allen and Unwin, Ltd.) 4s. 6d.

INDUSTRIAL POISONS

THE delivery by Dr. Donald Hunter of the Croonian Lecture of the Royal College of Physicians for 1942 was prevented by the War: but it is now printed (*Quart. J. Med.*, 12, 185; Oct. 1943). Remarking that the medical man of to-day must know something of the dangers of working in chemical, metallurgical, aircraft, munitions, ceramics, textile, cellulose lacquer and moulded plastics industries, Dr. Hunter points out that new materials for industry are frequently being discovered and used, and that their dangerous properties may not be realized until some workman loses his life or becomes severely ill. The medical man practising in an industrial area may have to deal with symptoms produced by substances which even the chemists may not fully understand. Such substances may attack the workman through his skin or lungs; some of them attack the liver, kidneys, blood or bone marrow. The toxicologist has to add to his medical equipment a considerable knowledge of chemistry and of the processes of various trades as well.

Dr. Hunter discusses the effects of lead, arsenic and mercury among the metals; among aromatic compounds he deals with benzene and its amino- and nitro- derivatives and also tri-*ortho*-cresyl phosphate; he concludes with the chlorinated hydrocarbons and substances of the glycol group. It is, of course,

impossible in a short article to summarize the results of experimental work and the wealth of other information contained in this lecture, which tells us many interesting things about industry as well as about toxicology.

It is interesting, for example, to note that the substitution of machine for hand labour has abolished lead poisoning among some kinds of lead workers and that, since 1899, the lead manufacturers of Great Britain have spent more than £200,000 on measures designed to provide healthier conditions for their employees. On the other hand, new methods and new industries have introduced new causes of lead poisoning. Motorists will note that spray painting of cars with leadless cellulose paints has reduced the incidence of lead poisoning in this trade, but the use of a lead and tin solder to strengthen steel motor-car bodies has created a new hazard. There is little risk of poisoning by the exhaust gases of car engines using petrol to which tetra-ethyl lead has been added, although it must not be used for cleansing the skin. Householders will be glad to know that aniline colours are now generally used to colour wall-papers, so that there is little risk of the symptoms once produced by living in rooms papered with wall-papers containing cupric arsenite. The mould *Penicillium brevicaule*, growing in the paste of such wall-papers, liberated dimethylarsine from the arsenical compounds used in the colours. It is worth noting, however, that, so late as 1931, a child died in the Forest of Dean from inhalation of dimethylarsine from the mouldy walls of a damp house, the arsenic having come from coke breeze used in the plaster of the walls. For this reason the use of concrete blocks containing coke breeze and the addition of arsenious oxide to cements to make them harden more quickly are not desirable.

It is in the field of the coal-tar derivatives that the toxicologist is hard put to it to keep pace with the chemist who produces them. Benzene, which must be carefully distinguished from benzine, is of outstanding importance, because of its destructive effect on the bone marrow.

Dr. Hunter states that medical workers all over the world are urging the abandonment of its use as a solvent. The same advice has recently been given by Drs. Hamilton-Paterson and Ethel Browning (*Brit. Med. J.*, March 11, 1944, p. 349). After two years of work on the effects of the inhalation of benzene used in rubber solutions in thirteen British factories, these authors conclude that some other solvent, such as solvent naphtha, should be substituted for benzene, which can cause permanent damage to the bone marrow; they recommend, among other precautions, that the blood of workers using benzene should be examined every six months. Further details about the effects of benzene are given by Dr. Hunter, who deals also with the dangers of the use of other coal-tar derivatives employed in industry.

It is interesting to learn that German factory workers at Münster, who were suffering from a shortage of fats, took home from their place of work a fat substitute and used it for frying potato pancake; they suffered from poisoning by tri-*ortho*-cresyl phosphate. In 1931, Continental women seeking abortion were poisoned by this substance, occurring as an adulterant of apiol, and in 1937 its presence in soya bean oil used for cooking caused other cases of poisoning in Natal. Many will remember the poisoning of some 15,000 people in the United States in 1930, when they took samples of a drink called Jamaica Ginger ("Jake") adulterated with tri-*ortho*-cresyl phosphate.

The chlorinated hydrocarbons will interest the general public because of their extensive use as refrigerants, fire extinguishers, cleaning agents and so on. Many of them are liver poisons. Carbon tetrachloride, which is the least harmful of them in practice, is used in fire extinguishers, in dry shampoos and as a household cleaning agent; it is also a valuable anthelmintic. The most dangerous of them is tetrachlorethane, which is also used in fire extinguishers, and as a dry cleaner and parasiticide. Its use for making waterproof coatings for aeroplane wings has been discontinued since 1917; in 1914 it caused poisoning of workers in this trade.

Dealing with substances of the glycol group, Dr. Hunter points out that, since 1925 or so, a great new aliphatic chemical industry has grown up, which is bigger than the coal-tar or aromatic industry, and this has produced a host of new solvents used in the textile, artificial silk, lacquer and celluloid industries, and in dyeing and dry cleaning and the making of paper, linoleum, polishes, cements and glues, cosmetics and other things. One substance of this group, dioxan, has a particular interest to laboratory workers, who may use it during the process of embedding material for section-cutting.

A bibliography extending to six pages adds greatly to the value of this detailed and very interesting paper. Apart from its value to industrial medicine, it should be read by the chemist, the manufacturer, the biologist and the social worker as well.

G. LAPAGE.

SMALL ERMINE MOTHS IN IRELAND

BRYAN P. BEIRNE has recently published an illustrated article* on certain species of these moths which belong to the genus Hyponomeuta. All stages of the three species, *H. padella* L., *H. cognatella* Hübn. and *H. evonymella* L., are distinguished; but the paper is mainly concerned with the biology and control of the first-named. In an outbreak of *H. padella* on hawthorn in Co. Dublin, an average of more than 95 per cent of the larvæ were destroyed by birds including starlings and other kinds. Of the remaining larvæ and pupæ about 50 per cent were killed by other enemies, including a species of Gregarina, which was found to be the most important single enemy of the larvæ after birds. Some 10 per cent and probably more were accounted for by this protozoan. An average of 3 per cent were destroyed by the well-known polyembryonic Chalcid parasite *Ageniaspis fuscicollis* Dalm.—the number bred out from individual Hyponomeuta larvæ ranging from 35 to 87. Some 3 per cent of the larvæ were also killed by the ichneumon *Angitia armillata* Grav. Less than 1 per cent were killed by other parasitic insects, including another species of Angitia, a species of Apanteles and what appeared to be Tachinid larvæ. A large proportion of the pupæ of the Hyponomeuta were killed by the predaceous larvæ of a sarcophagid fly, apparently *Agria mamillata* Pand. The ichneumon *Herpestomus brunnicornis* Grav. killed 8 per cent of the pupæ and *Pimpla turionellæ* L. 2 per cent of them. The immature stages of the parasites and predators are described and figured, together with

**Econ. Proc. Roy. Dublin Soc.*, 3 (Dec. 1943).

the adults of most of them. Some 4 per cent of the Hyponomeuta larvæ and 5 per cent of the pupæ died from unknown causes.

The causes of outbreaks of Hyponomeuta are discussed. Outbreaks appear suddenly, and it is thought that in a particular year the greater proportion of the larvæ escape attack by birds. Heavy outbreaks are always eventually controlled by parasites. But the parasites do not multiply at the same rate as the moths, and it is usually several years before they are sufficiently abundant to check an outbreak, and several additional years before they reduce it.

FORTHCOMING EVENTS

Thursday, March 30—Tuesday, April 4

BRITISH PSYCHOLOGICAL SOCIETY (at the Training Centre, Jordanhill, Glasgow, W.3).—Annual General Meeting.

Saturday, April 1

BRITISH ASSOCIATION OF CHEMISTS (LONDON SECTION) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Prof. R. G. W. Norrish, F.R.S.: "Chemistry and the Community".

Monday, April 3

SOCIETY OF CHEMICAL INDUSTRY (AGRICULTURE GROUP) (joint meeting with the FOOD GROUP AND LONDON SECTION) (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 2.30 p.m.—Mr. W. E. Rhodes and Mr. A. F. Davies: "The Selection and Pre-processing of Potatoes for Canning, with special reference to Control of Texture by Calcium Chloride"; Mr. F. Hirst and Mr. W. B. Adam: "The Processing and Laboratory Examination of Canned Potatoes".

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. R. N. Cotton: "The Planning of Working Hours".

ASSOCIATION OF AUSTRIAN ENGINEERS, CHEMISTS AND SCIENTIFIC WORKERS IN GREAT BRITAIN (at the Austrian Centre Swiss Cottage, 69 Eton Avenue, Hampstead, London, N.W.3), at 7.15 p.m.—Mr. J. Rubinstein: "Modern Trends in Electrical Insulation".

Tuesday, April 4

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Mr. J. W. Layard: "Song and Dance in Malekula".

Wednesday, April 5

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 2.30 p.m.—Sir Walter Langdon-Brown: "William Gilbert (1544–1603) and his Position in the Medical World"; Prof. Sidney Chapman: "William Gilbert and the Science of his Time".

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. D. Gabor: "Energy Conversion in Electron Valves".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

GRADUATE TEACHER OF GENERAL SUBJECTS, particularly MATHEMATICS—The Principal, Leicester College of Technology and Commerce, Leicester (April 5).

GRADUATE LECTURER IN MECHANICAL ENGINEERING at the Lincoln Technical College—The Director of Education, City Education Offices, 4 Lindum Road, Lincoln (April 6).

ASSISTANT MASTER or MISTRESS on the staff of the Day School to teach MATHEMATICS and some PHYSICS up to School Certificate standard—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex (April 11).

ENGINEERS with good Degree and some Research experience, preferably in HYDRAULICS, for Research and Development Department of large Engineering concern (location, Newcastle area)—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2011XA) (April 12).

DIRECTOR OF THE ART GALLERY AND MUSEUMS—The Town Clerk, Council House, Birmingham 1 (endorsed 'Art Gallery Director—Room 1') (April 12).

CHIEF ENGINEER, ELECTRICAL AND MECHANICAL, by the Jamaica Government Public Works Department—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.788A) (April 12).

LECTURER OF STATISTICS (temporary, full-time) to take charge of the teaching of Statistics—The Registrar, The University, Liverpool (April 14).

RESIDENT LECTURER IN CHEMISTRY—The Principal, Newnham College Cambridge (April 15).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

SENIOR LECTURER IN NATURAL SCIENCE at the Hull Technical College—The Director of Education, Guildhall, Hull (April 15).

HEADMASTER of the Junior Technical School, Doncaster—The Chief Education Officer, Education Offices, Doncaster (April 15).

ASSISTANT MASTER FOR TECHNICAL SUBJECTS in the Municipal Technical College—The Secretary, Education Office, Town Hall, Widnes (April 22).

CHAIRS OF MATHEMATICS, PHILOSOPHY and PHYSICS, tenable at Bedford College for Women—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (April 24).

ASSISTANT MASTER to teach MATHEMATICS at any stage up to University Scholarship work at the City of London School—The Town Clerk, 55–61 Moorgate, London, E.C.2 (May 1).

DRUMMOND PROFESSORSHIP OF POLITICAL ECONOMY—The Registrar, University Registry, Oxford (May 13).

W. H. COLLINS PROFESSORSHIP OF HUMAN AND COMPARATIVE PATHOLOGY—The Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2 (July 31).

BROADCAST ENGINEERS (male) by Government for service in Far East—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting Reference No. O S.90).

LECTURE ASSISTANT IN THE PHYSICS DEPARTMENT—Prof. H Dingle, Imperial College of Science and Technology, Imperial Institute Road, South Kensington, London, S W 7

ASSISTANT TEACHERS to take MATHEMATICS, MECHANICAL DRAWING, GENERAL SCIENCE, and GEOGRAPHY, in a Special Course in the Stroud District for R A.F. Students—The Secretary, County Education Office, Shire Hall, Gloucester.

PSYCHIATRIC SOCIAL WORKER for Child Guidance, Delinquency and other Child and Adult cases—The County Medical Officer, 4 Barnfield Crescent, Exeter.

ASSISTANT TEACHERS for (1) ENGINEERING SUBJECTS, (2) MATHEMATICS AND SCIENCE, at the Staple Hill Junior Technical School, near Bristol—The Secretary, County Education Office, Shire Hall, Gloucester.

THE INTERNATIONAL LABOUR ORGANIZATION AS A SOCIAL FORCE

A SIGNIFICANT passage in the recent report of the Conservative Central Committee on Post-War Problems, "Work: The Future of British Industry", recognizes the importance of strengthening existing institutions such as the International Labour Organization. The recent conference in London of the governing body of the International Labour Office has done something to bring more to the forefront a body the potentialities of which for reconstruction and the re-establishment of world order appeared to be in danger of being overlooked. Mr. Eden and other Government spokesmen have from time to time referred to those possibilities, notably in the debates in Parliament on economic reconstruction last year, but despite an admirable series of reports from the International Labour Office and the League of Nations, there have been few signs that practical steps are being taken to utilize the services of the International Labour Organization and to expand them where required to deal with the problems of relief or resettlement. The reference to the International Health Organization in the report of the sub-committee of the United Nations Relief and Rehabilitation Administration on policies with respect to health and medical care which has been included in the recently published report of that body* is not satisfying. While it welcomes co-operation with existing international health agencies and recognizes that the Health Organization of the League of Nations and the Industrial Health Section of the International Labour Office have much to offer on the basis of their experience and accomplishments, it does not encourage much confidence that such co-operation will in fact be fostered, or that new organizations will not be established where existing organizations might serve.

The decision that the governing body of the International Labour Organization is to meet and arrange for a full International Labour Conference next summer should dispose of the fear, entertained not without some reason, that the major Governments of the United Nations would allow the International Labour Organization to dwindle away in favour of new *ad hoc* organizations. The decision also represents, besides the preservation of continuity in international life, the formal association of employers and workers, as distinct from their governments, in post-war reconstruction. The bringing together of governments and occupational or technical groups, on which Mr. Bevin laid much stress in welcoming the delegates to the governing body at its opening meeting, may well be of decisive importance to the functional approach to international problems which now finds general favour, as well as in building up a moral force behind international law itself.

* United Nations Relief and Rehabilitation Administration. Resolution and Reports adopted by the Council at its First Session, held at Atlantic City, New Jersey, U.S.A., November 10 to December 1, 1943. (Miscellaneous No. 6, 1943. Cmd. 6497. London: H.M. Stationery Office, 1943. 1s. 3d.)

Much more indeed may flow from this termination of the neglect of the International Labour Office, for its brilliant studies and reports such as "The I.L.O. and Reconstruction", "Wartime Developments in Government-Employer-WorkerCollaboration", "Wartime Transference of Labour in Great Britain" and "Approaches to Social Security", have fairly established its reputation as a leading world centre, even during the War, for research into labour and social problems and for the dissemination of accurate and unbiased information. There must obviously be some adjustment of the relative spheres of, and the co-ordination between, the International Labour Office and the Relief and Rehabilitation Administration, the Permanent Organization on Food and Agriculture, and the other economic agencies to be set up. But beyond this, there must be hard thinking on the forms of international organization which the United Nations propose for the general welfare after the War.

If the International Labour Organization is to make the contribution to world co-operation and the elimination or minimizing of those strains in the economic and social structure of the world that tend to international friction and misunderstanding which the reports already referred to have suggested, important work must be done both at the International Labour Conference and before it meets. The growing social consciousness has strengthened the tendency to regard the International Labour Organization as a vital international agency and the desire for closer international co-operation in labour matters. Mr. Bevin asserted that the Organization must become the body charged with the duty of assisting governments by advice to give effect to that article of the Atlantic Charter under which the United Nations seek to "bring about the fullest collaboration between all nations in the economic field with the object of securing for all, improved labour standards, economic advancement, and social security".

It is true also that functional organizations such as the International Labour Organization are important means by which the smaller Powers can take their place and exert their influence in an international community; further, the method fits the circumstances of the United States, with its readiness to co-operate in practical work of the moment and its reluctance to make formal commitments. Nevertheless, there are important obstacles still to be overcome. The absence of Soviet Russia from the International Labour Organization, due to an old technical quarrel, is one; the attitude of American Labour is another.

To overcome these and other obstacles it is essential that the future status and policy of the International Labour Office should be clearly visualized, and this should be an early item in the agenda of the forthcoming conference. There must be unequivocable decision as to whether the International Labour Office is to be just an instrument for the co-ordination of information, or whether it may become a positive international instrument of co-operation for the improvement of existing laws and conditions, the regulation of labour supply, the protection of workers against sickness, old age, and accidents, industrial welfare and safety, and labour relations. There have been sharp reminders of the way in which a backward labour policy in even one of the United Nations may hinder the great war effort now demanded of us and delay victory, while in turning to face the problems involved in post-war reconstruction and a full employment policy, we cannot but be aware that the success of measures projected in Britain will depend on social, economic and labour conditions elsewhere.

For all that, a narrow view of the functions of the International Labour Organization is still taken in some quarters, and scientific workers are far from being alive to the extent to which this affects their own direct interests. Few of them have shown much appreciation of the work which the International Labour Office has done in such technical matters as industrial safety and health, accident prevention or the like, and its careful studies of the position of professional workers, of service agreements and like matters, have largely been ignored by their professional organizations. Moreover, the suggestion advanced by Sir Frederick Leggett on behalf of the British Government at the session of the governing body of the International Labour Office on December 18, on joint industrial committees on international lines, can scarcely have its full effect without their participation.

Sir Frederick suggested that the International Labour Organization could bring together employers and workers in the coal, iron and steel, engineering, building and civil engineering, textile and transport industries. He thought that great benefit would result from employers and workers themselves dealing with each other internationally, as they now do in national industry; and Sir J. Forbes Watson, welcoming a resolution for a revision of the constitution of the International Labour Organization submitted by the workers' group, urged that the Organization should not be too conservative. Its machinery clearly requires strengthening to fulfil the mandate implicit in the Atlantic Charter, and if there is to be a wide view of its functions, its machinery must be examined in a constructive and courageous as well as critical spirit.

Such a wide view of the functions of the International Labour Organization and revision or extension of its organization does not mean an extension into the high politics of economic affairs. The line may be hard to define at times, and in the economic and social sphere technical matters often tend to pass into the political sphere. None the less, in the future as in the past, the International Labour Organization will make its best contribution to the promotion of social justice and the adoption of humane conditions of labour as envisaged when it was first established if it keeps so far as possible within the technical field, and contents itself with purely advisory functions when political action by governments appears to be necessary.

If, however, those technical functions are to be exercised most effectively, the full support of all scientific and technical workers will be essential. That contribution must be made, in the main, through their professional associations, and it is to

be hoped that in approaching the problems of post-war reconstruction, as some of them are now doing, they will take a much wider view of professional activities and responsibilities than in the past. It is not merely that past neglect of the work of the International Labour Organization in the professional field must be remedied; there must also be a much clearer and more realistic view of the functions of professional associations than has characterized them in the past. They have a distinctive technical contribution to offer, which has sometimes been as readily thwarted by political proclivities as it has been by the innate conservatism of all professional associations. The meeting of the governing body of the International Labour Organization and the forthcoming conference give a direct challenge to professional workers for the creative thinking which must precede both the re-shaping of the Organization itself and the effective functioning of technical and scientific workers in a democratic system which will adequately serve the changing needs of the post-war world.

CONTROL OF CIVIL AVIATION

International Air Transport

By Brig.-Gen. Sir Osborne Mance, assisted by J. E. Wheeler. (International Transport and Communications.) (Issued under the auspices of the Royal Institute of International Affairs.) Pp. x+118. (London, New York and Toronto: Oxford University Press, 1943.) 7*s*. 6*d*. net.

UPON agreements among the nations of the world on the future development and organization of civil and military aviation may depend the very existence of civilized progress and freedom as we know them. Upon agreements among the nations of the world, by which they yield up some part of their national sovereignty to an international controlling body, may well depend a world organizing for peace. The failure to arrive at such agreements, the demand by each nation that its national sovereignty must be kept intact in the air, on the sea, and on the land, will ultimately lead to another world war, far more disastrous in its effects than the present one—one from which, indeed, the world may not recover for many generations.

These are strong statements to make, but a little reflection will lead to the conclusion that there is some justification for them; and very little knowledge of the past and possible future developments of air transport will convince those who acquire that knowledge that there is a very serious justification for the statements.

"International Air Transport" is an important book, for it supplies in a condensed, authoritative, logical and readable form just that information which all those who have not studied deeply the implications of air transport should have in their possession before they attempt to form public opinion, or worse still, take part in the laying down of air legislation. In its twelve chapters, the book contains the most concise, and documented, summary of the development of civil aviation, its failures and successes and its political repercussions, which has yet appeared.

The difficulty of arriving at a solution of international air traffic and control is nothing like so great technically as it is politically. In the past, civil aviation has been used as an instrument of policy, often closely linked with military aviation, and civil air lines have been used to give military pilots intimate experience of routes over which they have to fly in war. To quote from the book:

"Perhaps the most striking and extensive use of aviation for economic, political and military penetration was made by Germany in Latin America. Partly through the direct action of the Lufthansa, partly through numerous highly subsidized companies under Lufthansa control thinly veiled by national façades, partly through the grant of extensive long-term equipment loans to these virtual subsidiaries, and to other local companies when in need of financial assistance, German control of aviation extended to nearly every South American country. A large proportion of the technical and flying personnel were either Germans or Germans who had been nationalized in a South American country for expediency's sake. . . . An attempt was made to secure a contract from the Ecuadorean Government to operate a service to the Galapagos Islands which could have no possible commercial justification, but the Islands happen to lie in a highly strategic position just off the Pacific entrance to the Panama Canal . . . since the outbreak of war, German air activities in America have been largely eliminated by expropriation and other measures".

Now it could quite easily have been argued that this South American development on the part of Germany was purely the altruistic one of commercial expansion, and it may be a difficult argument to combat.

In the past, two methods have been suggested to control civil aviation with the view of abolishing also the chances of air warfare. One has been by international regulation and supervision of the manufacture and export of aircraft, and the other international organization of air transport. Attempts to carry out both these methods have failed; largely because it was believed that there was not enough difference between military and civil aircraft, and that any nation allowed to construct the latter could easily adopt them for the former. This reason is far less strong to-day than it was. Any present-day civil aircraft would make a poor military aeroplane for fighting and bombing purposes. But the danger still remains that civil transport machines, of the many varieties which will be developed, could be used for the transport of troops, munitions and guns.

It is becoming increasingly clear that only by some world-wide authority, overriding that of any particular nation, and provided with the necessary power to enforce its decisions, can the menace from the air be prevented; that is, the formation of an international air police force which would supervise the observance of civil air regulations and decisions regarding aircraft construction. As the authors point out, this police force would be quite different from whatever international military force may be created for protection against aggression.

The world stands at the cross-roads of aviation, and upon which road the nations decide to take may well depend the future of the world. It is to be hoped that the United Nations have already prepared the basis for an international co-operation and control which will prevent any nation becoming aggressively active at the terrible speed which aviation will enable it to be.

This is a book which should be widely read.

J. L. PRITCHARD.

FOOD-POISONING

Food-Poisoning

Its Nature, History and Causation, Measures for its Prevention and Control. By Elliot B. Dewberry. Pp. viii+187+17 plates. (London: Leonard Hill, Ltd., 1943.) 15*s*.

TO the Ancients, food-poisoning meant, as the name implies, the intentional adulteration of food with some deadly poison, and official food-tasters were still in vogue up to the Middle Ages. In the nineteenth century it was noticed that acute attacks of diarrhœa and vomiting followed the ingestion of certain foods, and the illness was blamed on ptomaines, the toxic alkaloids which are formed when foods are in an advanced stage of putrefaction. Later it became apparent that outbreaks of gastro-enteritis frequently followed the eating of apparently normal food, and just over half a century ago, when bacteriology was still in its infancy, Salmon, in the United States, and Gaertner, in Austria, showed that these alimentary upsets were due to certain bacteria (since called the Salmonella) and their toxins. About the same time van Ermengen, in Belgium, proved that the neuro-paralysis which frequently followed the eating of German sausage was due to the powerful toxin of an anaerobic sporing bacillus which he called *B. botulinus*, and the disease botulism. In the past fifty years much has been added to our knowledge of this type of food-poisoning, perhaps better called food infection or intoxication, and this knowledge has been collected and admirably arranged by Mr. Dewberry, together with sections on food-poisoning with metals, poisonous plants including the fungi, poisonous fish and shellfish, food allergy, and the contamination of food by war gases.

In dealing with the most common form of bacterial food-poisoning, that characterized by an attack of diarrhœa and vomiting within twenty-four hours of eating the peccant food, the author describes first the responsible bacteria—the Salmonella family, now more than 120 strong, certain Staphylococci, and certain strains of Proteus—some of which produce the syndrome early because the toxins are already formed in the infected food, while others, ingested with the food, produce their toxin in the gut, so that the onset of symptoms is delayed for 6–24 hours. The most common vehicles of infection nowadays are milk and milk products, or *prepared* meats (pies, sausage, brawn, boiled ham, etc.) which have been contaminated by human or animal carriers, and which act as culture media for these food-poisoning bacteria. Less often the infection is present before the animal is slaughtered for food and, because calves are particularly liable to Salmonella infection, veal is most likely to be infected in this way. The difficulty in sterilizing infected meat, particularly in a pie, is pointed out.

On the other side of the picture, the great improvement in the canning industry has meant that infection of tinned food before the tin is opened is now uncommon. No cases occurred among British or Allied troops during the War of 1914–18 despite the enormous amount of tinned food that was consumed.

In regard to sources and reservoirs of infection, Mr. Dewberry quite rightly stresses the importance of human convalescent carriers and mild 'missed' cases; but chronic Salmonella carriers must be extremely rare. Rats, mice and ducks are other sources of infection, and the house-fly, as carrier, must not be forgotten. The machinery for investigating and controlling food infections is fully discussed, with bacteriological technique given in an appendix. Food-poisoning due to the contamination of food with metals is, with the possible exception of lead and arsenic, quite rare, because metals are rendered inert by combination with the protein in the food. Botulism gets forty-eight pages, although it is a very rare infection in Britain—only one small outbreak has been reported since the Loch Maree tragedy in 1922. The organism is found in the soil of most countries, and, in recent years, many cases of botulism in America have been traced to infection from home-canned fruits and vegetables due to the fact that the spores of the organism require several hours' heating at 100° C. to destroy them. They are, however, much less resistant in an acid medium.

This is a book which in its lucidity and simplicity of language should appeal to the interested layman as well as to the medical expert. Its pages are enlivened by photographs of many pioneers in this branch of medicine, including a goodly sprinkling of Englishmen, but not, unfortunately, of Salmon.

ROBERT CRUICKSHANK.

PLASTICS

Plastics in the Radio Industry

By E. G. Couzens and Dr. W. G. Wearmouth. ("Electronic Engineering" Technical Monographs.) Pp. ii+58. (London: Hulton Press, Ltd., 1944.) 2*s*. 6*d*. net.

THIS, the second of the technical monographs issued by the publishers of *Electronic Engineering*, does not quite justify its title, for although it contains a full description of the types of plastics, their methods of manufacture and processing, and their general physical properties, their uses in the radio industry are barely mentioned. The authors, Mr. E. G. Couzens and Dr. W. G. Wearmouth, present the subject mainly from the point of view of the industrial chemist; that is, they describe plastics *for* the radio industry, rather than plastics *in* the radio industry. An amazingly gaudy frontispiece shows how dazzling to the eye is a collection of typical plastic products, but there is no discussion of their uses, and a natural desire to suppress some of the cruder decorative effects may blind one to the fact that brightly coloured insulating sleeving may serve useful technical purpose in identifying the elements of a complicated radio network.

There is, of course, much in the booklet to interest workers in the radio field, and perhaps it is legitimate to assume that they are already familiar with the kind of equipment for which such materials can be and are in fact used, and that what they most require is classified information on all the types they are likely to meet. This information is plentifully provided; the means of identifying the various plastics by heating tests, trade names and sources of supply are given, as well as the electrical and general physical properties. Experimentalists will be interested in the cements and solvents listed for the various materials, as well as some of the details of moulding, polishing and machining. A chapter on electrical properties is sufficient to outline the essential practical data, and to show the complexity of the relation between electrical properties and the factors such as temperature, frequency and molecular structure, which control them. Little attempt is made, however, to give a scientific discussion of this side of the subject.

MEDICAL AND SURGICAL ACHIEVEMENT IN THE U.S.S.R. DURING WAR*

By E. ROCK CARLING

When the fighting was at its height in Crete, 2,164 years ago, the people of Knossos applied to those of Cos, then the leading medical school in the world, for a military surgeon. Hermias, who was sent, did his duty so well that he not only saved many lives, but also by his example sustained the morale of the troops and thus contributed to victory. An inscription acknowledging his merits with gratitude is extant in Cos to this day, unless the Germans have recently removed it to grace one of their museums.

The duties of military doctors differ from those of their civilian colleagues. To relieve suffering, to save life, and to restore function, are indeed a part of their task; but there is an overriding duty—to keep every possible man in the firing line, and to return every possible man to that line at the earliest moment after injury or sickness. This may mean, for example, that a lightly wounded man has priority for attention over one so gravely injured that, though he recover, he will never return to the front.

More men leave the front as the result of sickness than of wounds. Sickness has determined many campaigns since that of Hannibal against Rome, and doubtless many before it. Thus a supremely important but undramatic part of the military medical officer's duty is concerned with sanitation in all its aspects, with such things as water supplies, and particularly with 'prevention'; from the control of flies, mosquitoes and other pests, to inoculation against specific diseases like tetanus, typhoid, yellow fever, and so on.

Modern implements of war, in their design, require the aid of physiologists and medical specialists if their full efficiency is to be achieved. It is idle to fabricate very powerful machines unless their control is within the physiological capacity of those who are to use them. In many cases elaborate measures must be devised to extend the limits of normal human functions. To endure extremes of temperature or to protect against them; to ensure co-ordination of the sensations and reactions in the atmospheric conditions of high altitudes and at great depths; to perfect the adaptation of vision to dim light; to control, or sometimes for offensive purposes to enhance, the means of illumination and dazzle; to protect against, and incidentally to find means to evade the possibility of protection against, flame as a weapon of offence; to perfect the means of audible communication amidst external din; to concentrate nourishment in palatable form within restricted limits of weight; to find means of minimizing the effects of rapid acceleration and deceleration of the body, and of the motions which produce sea and air sickness. These and many similar tasks called urgently for further consideration by several committees of the Medical Research Council in Britain at the outbreak of war, and concurrently with the rapid development of the machines have demanded continuing intensive research. The Russians have, so far, not emulated our other Allies in pooling the results of their researches; but it is certain from the success that has attended their corresponding weapons in the field, and indeed their whole military effort, that they have solved the problems which have beset us. Like ourselves, they have mobilized the resources of their physiological, pathological and other research departments to promote the efficiency of their military forces.

The Russian is a man with a realistic sense of the main chance, and the Soviet military surgeon, like others, believes in prevention at all costs. Thus it is that the Russian soldier of the Red Army finds himself better prepared to face the rigours of winter than his counterpart in the vaunted German military machine. If one sees, as one may, ill-shod folk in the streets of Moscow, it is because the soldier must have the best footwear if he is to sustain, in wet, cold and rough going, the sternest tests. No civilian in Russia grudges sacrifice or discomfort or hardship that is the outcome of the soldier's necessity. The Red Army is the darling of the nation. The people have unshakable confidence in it. It is perhaps the knowledge of the implicit trust reposed in them by their own people that inspires the Soviet soldier to such heroic deeds, to such wonderful feats of endurance. To have created such morale in people and army alike is one of the major achievements of Marshal Stalin and those who serve him.

Of the actual achievements of the Red Army doctors we shall not know in full until years after the War, when medical history is written. All I can do is describe what we of the Surgical Mission saw and did not see (though we looked for it), in our carefully conducted visit to the Red Army. In the South African Campaign I was plunged into a devastating epidemic of typhoid fever at its height. I know what it does to an army and the strain it puts upon the medical corps. In the War of 1914–18 I learned what a very different picture is presented at an advanced C.C.S. when wounded men are streaming in from victory or dragging wearily back from unsuccessful fighting. In this War it has been my rather tragic duty to witness in most of the heavily attacked cities the effect of bombing on civilians of all classes. I have been privileged to see and hear a good deal of the most modern accomplishments of our own and our Allies in war surgery and medicine. My companions on the Mission were men of similar experience and knew what to look for. With that background, then, what did the Russian picture reveal?

A first estimate of the achievements of military medicine in the U.S.S.R. may be deduced from the fact that the Red Armies are still in the field and victorious after retreats of depressing magnitude. There are authenticated examples in history of the collapse of good troops in the face of epidemic sickness and mass casualties, simply and solely because of the absence of a competent medical personnel. It is certain that the Russian soldier must have been well cared for; it is certain that the organization and the standard of service we witnessed must have extended, if not quite at the level chosen for demonstration to foreigners, yet at approximately that level along all the fronts, and throughout the territory to which troops found their way.

The People's Commissar of Health claimed that the U.S.S.R. have practically abolished two of the greatest scourges of armies in the field: one universal on modern battlefields—gas-gangrene—and the other, formerly endemic in a great part of the territory over which their fighting spreads—typhus fever. He told us that since the fighting began there has been no

* Substance of a Friday evening discourse at the Royal Institution delivered on February 25.

cholera. He also claimed that they get 70 per cent of their wounded back into the firing line—a figure not reached elsewhere. Probably we get between 60 and 70 per cent back into service, but not all of them into the front line. How have these feats been accomplished ?

I am not prepared to admit as yet that either typhus or gas-gangrene has been entirely prevented, or treated with such uniform success as might appear from the claims put forward ; but undoubtedly the Russians have controlled typhus epidemics where they might have devastated an army ; and they acknowledge the same methods we ourselves employ in the mitigation of gas-gangrene. It may be that they have other and better methods than those disclosed ; but so far, the allied medical corps are unaware of them, or of documented reports that justify confidence in their existence. On the other hand, the traditions of Russian research are so great, and the devotion of the Soviet authorities to-day to research in every field so intense, that there is nothing inherently improbable in a claim which perhaps can only be publicly substantiated after the War.

In connexion with those research traditions, one may consider three names, those of Mendeléeff, Metchnikoff and Pavlov. First. that of Mendeléeff, upon whose fundamental work much of modern chemistry rests ; remotely, but veritably, he laid foundations upon which modern biochemistry has been built, with all that the sulphonamide drugs have accomplished by way of lessening the horrors and the tragedies of the battlefields. It is not such a far cry from the recognition of atomic numbers and the Periodic Law to the production to-day by the ultrasonic generator of microcrystals no more than eight times the size of a red blood corpuscle by Prof. Paramanov. Nor to the fabrication of emulsions by Prof. Lossovsky, which, by the aid of chemical stabilizers, gradually dispense with more and more oil until they are almost wholly aqueous. Both these methods permit safer use of sulphonamides intravenously ; indeed, in one respect they have gone farther than we—injection into the arterial as well as the venous stream. This is the appropriate place to mention penicillin. The Russians having hitherto scarcely any supply, though our Mission took a small quantity, Prof. H. W. Florey has been sent to Moscow with a considerable quantity of the drug and all his knowledge. That is one of the gestures made by the British and American Governments to convince the Russians we are ready to put all our resources, all our discoveries in any science, at their disposal. Of course, we should welcome reciprocal trust.

Metchnikoff, who worked largely in Paris, made great contributions both to bacteriology and to the understanding of the natural defences of the body against infection, which we now exploit by every means that can be devised. It is in the tradition of his work that the attention of Russian research should be directed not only to the control of infecting organisms by bacteriophages and bacteriostatic agents, but also to new methods of stimulating the defensive mechanism. For that purpose they are exploiting 'activators' of various kinds. Prof. Bogomouletz produces sera by injection into horses of splenic and lymphatic tissue, and finds that their action upon mesoblastic structures, particularly the vascular network, materially stimulates repair. They use the sera to promote healing of gastric ulcers and also to diminish the period of repair of wounds. They claim something like a 20 per cent reduction of invalidity-time in cases of fractures and gross soft-part wounds.

They have other methods of producing the same effect, by burying under the skin partially ischæmic cutaneous flaps or placental tissue prepared by a chemical treatment. Extracts of placental tissue are also employed to hasten the 'taking' and the growth of skin-grafts. We saw these methods in use in the wards of Profs. Louria and Friedland.

Pavlov, whose contributions to physiological psychology introduced the element of measurement and exact observation necessary for all scientific advances, clarified a wide field of mental processes ; he trained a school of Russian psychologists whose labours in their turn have been fully employed by the Red Army medical authorities in the training, conservation and care of their man-power. One example from their system of rehabilitation of the lightly wounded soldier struck me forcibly. These men go to special hospitals where curative measures, both operative and physiotherapeutic, are employed. There, 'education' accompanies their progress and serves a twofold purpose. A man may return to his regiment fully restored to his former vigour ; but he rejoins men who have had further experience that he has not shared. To that extent he is at a disadvantage and his sense of this particular inferiority may be deflected to the past disability, which he had far better forget. The Russians, therefore, see to it that his rehabilitation education shall make him more expert than ever in the use of his weapons ; better acquainted with the enemy methods and weapons he has to meet, and familiar particularly with the latest type of offensive machines of all kinds, and with the drill necessary for their most effective use. He then goes to his regiment with something his comrades do not possess, the last word in means for defeating and destroying the enemy ; he has at least one source of superiority and his morale is that much heightened.

Even to so elementary a medical requisite as cleanliness, the Russians add a psychological twist. Wounded men come in extremely dirty and often with several days' growth of beard. So, upon entry to the reception ward they find a 'barber'—not an orderly turned hair-cutter but a professional *coiffeur* who shaves them skilfully, cuts and shampoos the hair and starts the sequence which restores a man's self-respect. Thence they pass, after a drink of vodka, to the care of nurses, who bathe those who cannot manage for themselves—they have a real nursery 'tub'—and provide them with a clean set of underclothes or pyjamas. Only then, when they feel respectable again, does examination, sorting, dressing, begin. The cleanliness and warmth go some way towards 'resuscitation' of cases suffering largely from the fatigue, exposure and thirst which account for a good deal of the minor degree of shock. Of course, some cases are far too seriously ill to undergo this whole process ; but wounds as such are no bar, for they are covered with waterproof bags or 'jackets', and in the case of broken legs the patient is put upon a slatted wooden stretcher before immersion and the limb can be completely steadied by ties to the slats. A good wash restores morale. These examples, trivial as they are, illustrate the realistic attitude of the Russians and the intelligence with which their problems are attacked. Their psychology, theoretical and applied, is far from being at fault. Perhaps the success of their propaganda has prepared us for appreciation of their psychological methods with the soldier.

In my youth there was a famous book (Hilton on "Rest and Pain"), the theme of which was advocacy of immobilization; it held sway and governed practice for a generation. "Rest must be secured if pain is to be abolished." The pendulum of opinion swung and the supreme importance of early movement after injury was taught by the foremost surgeons of the day. We all know rather more precisely now when to employ rest and when movement.

In the recent Spanish War, a very well-known surgeon of Barcelona, Trueta—happily and fruitfully working among us now—advocated the treatment of gross injuries of the limbs, and especially fractures, by so close an application of plaster-of-Paris cases that all movement of the muscles of the limb was inhibited. Called the 'skin-tight plaster', it fitted like a glove. He advocated and secured 'rest', and the immobility of the muscles was so perfect that the pumping action which they normally exert upon the veins and lymphatics was abolished, and thus poisonous substances fabricated in the wounds failed to reach the general circulation, where their toxic effects would endanger the life of the patient. The principle is one which makes imperative meticulous observation of certain essential preliminaries in the way of operation and treatment; but in appropriate circumstances, the method is now very widely used in the Allied Armies and probably in those of the Axis, too. There was an earlier protagonist of a form of this expedient, an American, Winnett-Orr, to whom surgery owes very much, but the actual initiator of the close-plaster was a Russian. Pirogoff, whose name is known to every British medical student as the originator of a particular type of amputation which bears his name in our text-books, has been described as the "greatest Russian surgeon, and one of the greatest of all military surgeons". He used plaster-of-Paris for fractures in the Crimean War. He had noticed the use of plaster by a sculptor and realized at once how it could be adapted to war injuries. He wrote repeatedly on the subject, but years later lamented that neither French nor Italian military surgeons knew of his method.

Pirogoff's contributions to surgery were many. One more may be mentioned. Perhaps only after hearing of Florence Nightingale, but at any rate, in the Crimean campaign, with the help of one of the Grand Duchesses, he introduced nurses into military hospitals of the Russian Army.

Nursing means rather more in Russia at war than it does with us. Not more than our nurses would certainly volunteer to do did the necessity arise; scarcely more than they were ready to do in North Africa; but the position of women is a little different in the Soviet State in peace as well as in war. It is, I think, fair to say that the concession to women in the U.S.S.R. of exactly the same 'rights' as men has led to the full acceptance by them of their implied duties. Nurses go not only to the front-line hospitals, but also up to main dressing stations and into the line itself. They reach wounded men under fire, and drag or carry them to safety, and even if need be, defend their patients from enemy attack.

On our way to the front we found all the main road-crossings guarded by women soldiers carrying tommy-guns, and it was obvious that they would not have stood upon ceremony if our cars had not promptly obeyed the 'halt'! We did not, at the clearing hospital, see any armed nurses, but many women have been decorated for feats of bravery.

Of the versatility of the Russian nurses we had evidence enough. The story of their prowess with the axe, saw, plane and spade is now well known, and we witnessed it. The 2,000-bedded hospital in the pine-forest had at the time of our visit only about 700 patients, but the Orel advance was about to begin and expansion to 4,000-bed capacity was under way. The nurses not needed for their professional work were taking a full share in all the labours of construction, foundation digging, timber squaring, carpentry, camouflage and decoration. Very deft with their tools they seemed to be. It must not be forgotten that for our entertainment that evening those same women staged a very good cabaret show.

To judge of their proficiency in their proper sphere we had opportunity in operating theatres. It was manifest that the standard of the theatre sisters and their staffs was very high. As surgeons we felt that we should confidently work in theatres run by those women. In no hospital that we visited did we observe evidence of poor ward-work. Their bedsteads and mattresses are not so good as ours, and that makes nursing more exacting; demands more conscientious attention to detailed care; and I think we are entitled to infer that nursing is well done.

Organization is a strong point in the Russian of to-day. The basic plan of military hospitals is flexible; they are planned in units which may be grouped or detached at will; the staffing is so systematized that a unit sent forward from a base hospital can take over the whole or a section of a forward post. They have aimed at 'leap-frogging' as a means of maintaining continuous service in advance or in retreat, so that the supreme requirement of getting the wounded early to operation can be fulfilled in all circumstances. In our own North African war, with characteristic capacity for putting a telescope to a blind eye, the British overlooked the rules laid down in the manuals and improvised just such a leap-frogging plan—section by section—to the great betterment of a threatening situation. Necessity, with us, mothered invention; the Russians planned it in advance. Moreover, they have so arranged the segregation of all regional wounds in their forward clearing hospitals, into the care of front detachments of the staff of their head, chest, abdominal, plastic and orthopædic hospitals, that the patients fall at the earliest moment into the hands of those who will initiate specialist treatment. The same 'teams' will have members away in the far rear, to whom long-stay cases are sent, and thus the whole course of a soldier's invalidity can be controlled and studied by the same specialist staff. There is no doubt that such a system, if the nature of the warfare permits its adoption, is the best devised for saving not so much the life as the full function of the wounded. This, perhaps, is one of the means by which they secure so high a percentage of return to full duty. By contrast with the Soviet success in this respect, one may compare the results on the same ground a century and more ago.

In Napoleon's campaign of 1813, out of 22,000 French soldiers admitted to certain hospitals during May 1–June 1, 6,700 officers and men were known to have returned to active service in their units: just over 30 per cent. Another 20 per cent were capable of some duty; the total figures may have been higher in both categories, but certainly did not approach the modern Russian claim. Moreover, there were 972 amputations in that one month—tragic testimony to the prevalence of gangrene. 2,400 died, that is, more than 10 per cent of those reaching base hospitals.

These French figures were given by the great military surgeon Larrey, of whom Napoleon said, on leaving him 100,000 francs, that he was the most virtuous man he had known. Of cases reaching our own base hospitals in some recent actions, the deaths were little more than 1 or at most 2 per cent.

I have sat at a table in a clearing hospital behind the front with a woman surgeon wearing five wound stripes, and in the same hospital saw a woman operating on chest cases, of which she had done more than a thousand. Many women doctors have been decorated for bravery. It is perhaps of interest to mention that whereas in peace 50 per cent of medical students are women, now in war they number 85–90 per cent of the 24,000 a year being trained. 16,000 young military doctors, of both sexes, were given special courses in military medicine in 1942.

Another test of efficiency that may be applied is the recognition of problems of major importance in modern military experience. One of the most valuable of all modern methods for saving the life of the wounded soldier is blood transfusion, and here the Russians have been no whit behind us. Their methods for the collection, preservation and distribution of whole blood, their preparation of dried blood constituents for reconstruction in the field, and their many plasma substitutes, indicate very clearly how early and how thoroughly they were seized of the immense life-saving value of this means for controlling 'shock'. A minor measure reveals their appreciation of a psychological factor. The blood is mainly given by women —95 per cent of it, we were told. To the ampoule of blood the name of the girl donor is attached. She knows the wounded Red Army man will hear of her. He knows to whom he is indebted. Romances result and are broadcast for their full propaganda worth. The man who has once benefited, if he be wounded again, asks for the same life-giving blood once more. Blood donors in Great Britain may be interested to know that after tests, and on arrival at the taking station, all women are clothed in sterile garments, caps and masks, before admission to one of the four theatres kept for the four blood groups. They are given a light meal, without fats, just before the blood is drawn. In another station the donor does not enter the theatre at all, but lies upon a couch and thrusts her cleansed arm through a sterilely curtained window into the room where the blood is taken. The arrangements are on a vast scale and thought out to the last detail. As many as eight hundred donors are bled daily in one institute. The headquarters of the Blood Transfusion Service has seventy-nine subsidiary institutes under its control, with 1,500 minor stations. Preservation of the blood calls for methods adapted both to the duration required and to the means of transport. When taken by air at high altitudes or in the very low temperatures of winter, special insulating boxes must be used. Distribution is generally by air.

As to other pressing problems, we were fortunate enough to obtain first-hand evidence from distinguished research workers. The Academicians Orbeli and Lena Stern, whose studies have for long been devoted to the elucidation of the functions of the autonomic nervous system, are probably responsible for the orientation of Soviet thought towards neural rather than biochemical predominance in normal and disturbed metabolic functions.

The former, Orbeli, has among other applications of his research, turned to advantage his long studies of the phylogenesis of parts of the nervous system in relation to dark-adaptation of the eye, especially for night-pilots, using his differential study of the rods and cones, and of the Purkinje effect, to that end.

Lena Stern, the only woman Academician, has tackled a problem that still eludes complete solution. It is recognized that in some cases of what we loosely term 'shock', a phase is reached when no amount or kind of transfusion is effective. The dynamics of the circulation have been disturbed to a degree which is 'irreversible'. It is a stage desperate as regards the patient's recovery, and justifies desperate remedy. Stern believes that the 'irreversibility' is dependent upon a complete loss of tone of the musculature of the whole vascular system. She believes that tone is ultimately controlled by centres bordering upon the cerebral ventricles; probably the fourth ventricle particularly. Potassium stimulates the sympathetic and calcium the parasympathetic. She therefore forcibly injects into the cisterna magna, and believes that she thus directs into the ventricle a sterile solution of potassium phosphate; the potassium for its direct effect, the phosphate radical to form, with calcium already present, a non-ionizable and inert compound. An injection into the cisterna magna, except in very expert hands, and in conditions giving guarantees against infection, is not a method to be lightly employed. The syndrome it is sought to remedy is met with within a matter of hours after wounding and exposure; met with, therefore, most frequently before the victim arrives at a well-stabilized hospital, and the remedy must be chiefly useful, at any rate until its value is very thoroughly established, in the hands of experts who reach the forward positions. Prof. Stern stated that a considerable number of reports of success with her method had reached her, but among Russian surgeons generally its use, we gathered, is regarded as experimental. Incidentally, Prof. Stern told us that she had had success with the treatment of tetanus by the cisternal route. In man many severe cases had been cured, and in horses there was a 100 per cent recovery.

As with the Russians, so among the other Allies, the factor of fluid loss in shock has been in the foreground of the picture, but in recent years there have been periods when the neurogenic factor has been enthusiastically pursued here; its importance, however, has never gained unquestioned credence. The 'toxic' factor, to the importance of which Sir Henry Dale directed attention twenty-five years ago, and to the investigation of which his researches lent such impetus, has again come right into the foreground and is engaging a great deal of attention. The Russians have not entirely overlooked this possibility.

We were interested in one method of treatment which runs contrary to all past experience, ours and their own, for frost-bite. It has been the universal practice, of mountaineers as well as soldiers, to avoid rapid warming of parts involved. To rub gently with snow; to warm the rest of the body, perhaps, but to keep the frozen or menaced areas cool. The Russians now put the patients into a well-warmed ward and deliberately heat the frost-bitten limb. They believe in early excision of dead tissue, and, we gathered, in early amputation, and that may possibly be part of the explanation: they cut their losses. But they maintain that their method has a sound physiological basis.

In 1812 Larrey said that the hospitals of Moscow, both military and civil, were the finest he had ever seen. That could not be said to-day of those we saw. The

buildings are not recent. It is an item to which the Soviet has not yet fully turned its planning attention. When it does so, it is certain that the structures will be determined by function and leave nothing unfit for comparison with the best of other countries. The scale upon which the Russians think is illustrated by their projected great Research Institute, V.I.E.M. It was intended at first to erect it in Leningrad, but afterwards Moscow was decided upon. The plans are, as they themselves say, grandiose. With only five hundred beds for the intensive study of normal health and somatic disease, they provide approximately a hundred sets of laboratories or departments and 1,300 workers as a beginning. Since every medical student proceeding to an M.D. must present the results of research, which with clinical work normally spreads over six years, the laboratory space, technicians and directors of research must be provided on a great scale. A Red Army convalescent home provides another example of the scope of Russian planning.

When it comes to military hospitals in the forward zone, we were witnesses of their skill in construction, their admirable camouflage, their adaptability and the excellence of their improvisation. It was in a pine forest just beyond Vyasma that we found the clearing hospital already mentioned. We came upon it without realizing that any building, let alone a great hospital, was anywhere near. They also have tented hospitals in the forests—of two hundred bed capacity for each of their specialist departments. Camouflage is essential, since on the Russian fronts the German does not observe the Geneva Convention. It entails two hardships upon the wounded even if the hospitals are not attacked. Smoke must not rise to give away a position and that makes contention with winter cold very difficult. There must be no metalled road running to the site, or the first reconnaissance plane will detect something to be attacked. This means a very uncomfortable and sometimes agonizing ambulance ride over the last mile of track.

We came in contact here with the partisans and guerrillas, who when wounded were regularly fetched in from their concealed collecting points by air. So complete is the organization that dentistry for those behind the German lines seemed quite a natural provision ; they make the denture in Moscow, to the mould brought in by air, and fly it back forthwith. The dental department of the Red Army has made enormous numbers of dentures for the troops on every front. In that attached to one facio-maxillary unit we visited, more than a million dentures had been made for soldiers. Artificial limbs, too, are made on a scale commensurate with the size of the armies. Those we saw were entirely constructed of wood, and to our thinking a little on the heavy side, but mechanically good.

No account of medical service in war would be complete without reference to the preparations for dealing with casualties in bombed cities. It is true that we have no towns comparable for utter destruction with Stalingrad and Vyasma, to mention only two that we saw for ourselves, though there are so many others in like plight. But in Moscow there is, judging by experience in Great Britain, little sign of bombardment, and the civil defence arrangements are not so much in evidence. We saw one control room, which had been used for bomb casualties, but it existed in peace, and enables every accident or acute emergency in Moscow to be brought to the great emergency hospital or to one of its six satellites. We watched three calls. From the receipt of the message to the dispatch of an ambulance with nurse and doctor aboard, the average time was one minute forty seconds. It would be difficult to better such a system, but I must add that with our own bitter experience in mind, I was disappointed to be told they had no organized messenger service to replace the telephones when an unlucky or well-directed bomb fell upon the exchange. I have no doubt that had the need arisen in Moscow a service would immediately have been improvised, and I expect Leningrad would tell a different tale.

Among the men responsible for Soviet achievement in the section of their life under review there are three whom we met whose characters suggest the basic reason for success.

The director-general of the medical corps of all the Russian armies, Lieut.-General Smirnov, is a man of thirty-seven. He is a big, fair man whose face can be expressive of determination, of irony, of humour. It is stated that as a child and youth he had no education and was employed in labouring work. Between twenty and twenty-four he fitted himself to enter a medical school. He qualified at twenty-nine. In eight years his ability has raised him to the highest administrative post in the medical services, and we were informed by an Academician that, in addition, his purely professional attainments were held in high esteem by men of science and practitioners alike.

The chief consultant surgeon, Lieut.-General Burdenko, is a man whose energy has enabled him to triumph over a personal disaster to his health that would have ended the career of a lesser man. He has inspired in his pupils and his assistants an unassailable devotion. It is evident that his opinion has moulded current military medical thought and practice. His own particular interest has been neuro-surgery, and it is to him that is owing the very active research in that department now so fruitful in Russia. He told us with pride that from front line to far base he had seven thousand beds for neuro-surgery, and we had evidence from Profs. Rappaport, Propper-Grashenko and Schlikov of the intensive study devoted to the occupants of his wards. Operative surgery on the central and peripheral nervous systems as we saw it practised is perhaps lacking in the refinements now the rule in American and British units, but the neuro-surgeons with us recognized that some of the records made at the front were as good as any they had ever seen, and they felt that the skill and ability were not lacking in the young men to permit their quickly reaching the highest proficiency.

In Prof. Yudin, head of the famous Sklissosovsky Hospital for accidents and acute emergencies in Moscow, Russia has an abdominal surgeon who would lend distinction to any clinic in the world. His experience is immense ; in some respects unique. His courage is matched by his gentleness ; his skill by his untiring devotion. It is characteristic that in war he should go often to the front and there devote his abilities to perfecting and teaching others the technique by which that most disabling of curable wounds, compound fracture of the femur, can best be treated. Watching this man at work, studying the conditions of work he has created about him to ensure success, seeing the subjects of his most daring and extensive operations a week after operation, we could not but feel that the service which has such a man, nay, such men, has a source of inspiration

which has carried it far, and will lead it to great heights.

Russian military medical officers have maintained their armies in the field without the occurrence of any epidemic disaster; they have enabled their soldiers successfully to use the most powerful and elaborate of war machines; they have cared for the wounded so skilfully as to obtain a record recovery-rate; and they have sustained the morale of their troops through a period of devastating tribulation to the dawn of a triumphant advance.

What more could be asked of the army medical corps of any nation?

INTER-RELATIONS OF PLANTS AND INSECTS

IN opening a joint discussion on "The Inter-relations of Plants and Insects: the Place of Both in the Eco-system" between the British Ecological Society and the Royal Entomological Society of London held on November 12, Prof. E. J. Salisbury claimed that though the insect – flower relations have been extensively studied, the quantitative aspects of insect-pollination have been little explored though economically important, while the competition aspect has been largely ignored. The elaborate and familiar relation between the yucca moth Pronuba and *Yucca filamentosa*, in which the reproduction of each is dependent on the other, but the larvæ take a high percentage of potential ovule production, serves to illustrate how narrow may be the margin between benefit and disadvantage in the relations between insects and plants.

The relations of insects to plants as pests or predators set many questions that require answers. Why, for example, are some insects almost omnivorous, whereas others are confined to particular species? Familiarity with human preferences obscures the fundamental problems waiting to be investigated. Something of the complexity of the problem is indicated by insect larvæ which in the wild state are found on one food-plant only but in captivity can be reared on a variety of species. An analysis of the physiological basis for such preferences might well yield data of great practical importance in the field of horticulture and agriculture. Whether a plant species in the British Isles supports the same insect population as the same kind of plant in continental Europe is also a matter of great biological interest. For the nature and variety of the insect predators and pests to which a plant species in Britain is subject may be an important indication as to the length of time that the plant has been present in these islands or, on the other hand, as to the efficiency of insect dispersal.

The influence of man has created in the past, and is constantly creating in the present, habitat conditions where the pressure of competition is reduced or even negligible, and the species associated with the arrested successions thus artificially maintained have been frequently regarded as under suspicion of being introductions. But the species which to-day we find most frequently occurring in, or even confined to, artificial conditions, may be those which in former times were to be met with in similar though much less frequent conditions created by natural agencies. On the other hand, they may represent what may be termed domestic species which have arisen since the widespread occurrence of such habitats, and in some instances may have extended into natural habitats of a similar character. This might appear to have little concern with the relations between plants and insects were it not that both groups of organisms present the same general problem, and an intensive study from this point of view of such very interesting series as that presented by the group of house spiders and their allies might well shed light on the fundamental problem. The domesticated flora and fauna not only deserve more attention than they have hitherto received, but also attention to the relations of both might reveal what the study of either alone could not achieve.

Dr. E. A. Cockayne discussed a number of Macrolepidoptera which are limited by special plant species. Many species of moth are attached to a genus rather than to a species, and others eat two or three plants belonging to allied genera, such as Fraxinus and Ligustrum, Calluna and Erica, Urtica and Humulus, *Silene maritima* and Spergularia. Oak has more species of Macrolepidoptera restricted to it than any other plant; they are eighteen in number and belong to several families. In the case of many larvæ limited to a single plant species, the latter is the only representative of the genus found in Great Britain, but on the Continent, where other members of the genus occur, these also are eaten; for example, *Bupalus piniaria* is confined to *Pinus sylvestris* in Britain, but eats other species of Pinus on the Continent. Other examples of genera with only one native species are Fagus with one species of moth restricted to it; Alnus with two; Clematis with five; Euphrasia with two; Eupatorium with one; Serratula with one; Solidago with two; Phragmites with nine; Elymus with one; Ammophila with one. On the other hand, *Ulmus campestris* has two species peculiar to it and *Ulmus montana* has two others; *Carex glauca* has one; *Calamagrostis epigeios* has two; *Festuca arundinacea* has one; *Deschampsia cæspitosa* has one; *Artemisia absynthium* has one, and *A. maritima* has two; *Lysimachia vulgaris* has one, and *Convolvulus arvensis* has three. In such cases the selection of one species of a genus is usually due to a difference in ecological conditions.

It is interesting that most British moths with a very restricted range are not restricted because of the absence of a special food-plant. *Anepia irregularis*, however, has the same narrow range on the Breck sand as its food-plant, *Silene otites*, and it is probable that the limited south-western range of *Drepana harpagula* is coterminous with that of *Tilia parvifolia*.

Some British Lepidoptera have reached the northern or western extremity of their distribution and have become limited to special ecological conditions or to a special food-plant. *Papilio machaon* is found only in the Fens, and feeds chiefly on *Peucedanum palustre*; while abroad it is found in all kinds of country and feeds on many umbellifers; *Malacosoma castrensis*, an inland and woodland species on the Continent, is only found in the salt-marshes of south-eastern England, though it feeds on most of the plants which grow there. *Brachionycha nubeculosa*, which feeds on many kinds of tree abroad, only eats *Betula alba* in its local haunts in the Highlands of Scotland.

There are instances of biological races with different food-plants. *Eupithecia denotata* eats the seeds of *Campanula trachelium*, and its race *E. jasioneata* eats those of *Jasione montana*, while *Hydrelia flammeolaria* eats maple in the south and alder and mountain ash

in Scotland. The distribution of the two plants might explain the former case, though it is not clear why other species of Campanula are avoided; but there is no obvious reason for the different food-plants of the Hydrelia in the south and in the north. *Plemyria bicolorata* eats rose, blackthorn, crab apple, birch and alder in England, but in Dr. Cockayne's experience, only alder in the north of Scotland.

Captain C. Diver spoke of insects limited by the general conditions imposed by plant communities. The good field naturalist undoubtedly knows where and when to look for the species in which he is interested. This apparently intuitive recognition is the subconscious crystallization of innumerable small impressions and experiences revealed by his acute powers of observation and slowly built up by his memory into a complete picture. Knowledge of this kind is fundamental to a clear understanding of some of the major problems of biology, whether pure or applied. No progress can be made in the study of animal and plant populations, distribution, colonization, plagues, the control of pests, and so on, until we can give a proper answer to the question why this place is 'right' and that place is 'wrong'.

After giving examples of the simpler aspects of this problem from among Lepidoptera, Odonata and other groups, Capt. Diver went on to consider two genera of hover flies investigated at Studland Heath in Dorset. There occur at Studland seven out of the nine British Helophilus and ten out of the eleven Eristalis. The larvæ of both these genera can be stated broadly to live in stagnant wet conditions; but the adults require additional amenities which are not all present in the places where the larvæ can live; and if these are not represented in neighbouring habitats, places where the larvæ could live are not likely to be occupied by permanent populations.

The adult Helophilus generally stays closer to the larval habitat than does the adult Eristalis; but it requires the structure of the vegetation to be such that this provides sheltered flying places, and preferably a fair supply of flowers to visit. Helophilus will not normally be found hovering or laying in the type of marsh where the vegetation over a large area is uniformly short, which means that there is no shelter from wind at heights above a few inches from ground level. What these flies seem to like is an uneven structure giving a good mosaic of patches of short and tall vegetation, the air above the former being protected by the wind-breaks made by the latter. It does not appear to be so important which plant species are present as that some should be tall and some short; although a good flowering population of *Potentilla palustris* Scop. is an added attraction for the less adventurous species, provided it is growing in a sunny and reasonably sheltered spot.

The species of Eristalis vary more widely in their needs; though most species are inveterate flower visitors, and the commoner ones are on the wing from the flowering of the sallow to the flowering of the ivy. But they need also the right conditions for hovering. *E. aeneus* Scop. and *E. sepulchralis* Linn. can tolerate the low vegetation and exposed conditions of salt-marshes, where they hover close to the ground. *E. intricarius* Linn. tends to hover high, but does not apparently demand good wind-breaks. While *E. pertinax* Scop. and *E. tenax* Linn., which usually hover at heights between 4 ft. and 8 ft., seem to find their optimum for this exercise in sheltered woodland glades. The primary characteristic of a woodland glade for this purpose is precisely the same as that required by Helophilus in the marsh; that is, an area of relatively low vegetation surrounded and sheltered by taller species. But unless these glades are of sufficient size relative to the height of the trees so as to get full sunlight, they will not provide good conditions for these species. Eristalis seldom hovers in the dapple light under trees. These sites are occupied by other Syrphids, particularly the common *Syrphus ribesii* Linn. and *S. vitripennis* Meig.

The width, the complexity and the difficulties of the general problems raised by these few illustrations need no stressing; there is here an immense and fascinating field for careful observation and research. As a final plea, Capt. Diver urged that, though it is highly important to call a species by its right name according to the rules, it is even more important to know where and how that species lives, and why it chooses to live where it does.

Dr. C. F. C. Beeson dealt with the influence of insects on the regeneration, composition and destruction of forests. Virgin forests are characterized by freedom from insect epidemics, but catastrophes due to external factors may release destructive forces latent in endemic phytophagous insects. Seed insects are less important influences on the regeneration of forests than are insects feeding on the seedling and young sapling. The composition of a tree community is determined largely in early youth but may be modified later by insects. "Pure forests are more liable to outbreaks of insect pests than are mixed forests" is an axiom of forestry. Virgin tree-associations, which are immune, are protected by components of the field stratum. Mixed forests derive immunity from complex interactions based on structural and floristic characters. The composition of a mixture from the aspect of crop protection can be defined in terms of its primary and subsidiary insect communities.

In the subsequent discussion, Dr. H. Godwin, president of the British Ecological Society, mentioned that the British Ecological Society has just begun publication of a "Biological Flora of the British Isles", which should prove of especial interest to entomologists.

Prof. P. A. Buxton directed attention to the interesting differential reaction of insects to associations of native and closely related exotic plants growing near together. He instanced the fact that the sawfly so familiar on *Iris pseudacorus* spreads to some cultivated Iris spp., but not by any means to all. Mr. B. D. W. Morley recounted similar observations made on *Aphis fabæ*, the usual winter hosts of which are *Euonymus europæus* and *Viburnum opulus*. The species has also been observed on some, but not all, foreign species of Euonymus growing in various nurseries and botanic gardens, and Mr. Morley suggested that physiological changes brought about by approaching leaf-fall may prove to be one of the factors affecting the choice of host-plant by the aphis. In this connexion Mr. A. J. Wilmott emphasized that very varied reasons may decide why a particular insect feeds on one or more species; even if Mr. Morley's explanation that leaf-fall is the decisive factor concerning *Aphis fabæ* be accepted, many other factors must also be operative.

Prof. Hale Carpenter asked how it is that bark beetles, normally attacking only unhealthy or dying trees, are able to become a pest to healthy trees. Do trees normally produce some deterrent preventing the spread of bark beetles, which the beetles by insistent attack in great numbers are able to overcome? Do

trees cease to produce a deterrent, or do the beetles become by degrees less affected by constant exposure to it? Dr. C. F. C. Beeson replied that trees certainly do react to these attacks, but not to such an extent as to be able to control large-scale attacks.

Dr. W. H. Thorpe referred to the probable influence of parasites in reducing or eliminating a polyphagous host species on certain of its food-plants. In this connexion he directed attention to the desirability of placing on record, with as much detail as possible, particulars of differences in percentage parasitism associated with different food-plants. Dr. B. Barnes remarked that just as related species of insects attack members of Rosaceæ and Salicaceæ, so do related species of fungi; he stressed the need for biochemical investigation.

Prof. H. G. Champion emphasized the point made by Dr. Beeson, that the influence of insect attack on the specific composition of vegetation is relatively greater in the earlier stages of plant colonization or succession, when the competition between species is most severe, and it may take very little to tilt the balance one way or the other.

On the more general aspects of the subject, Dr. G. C. Varley suggested that problems of numbers, or of animal or plant distribution, are insoluble until the fundamental problem of what factors control the population density of the species of plant or animal in the community have been solved. He believes that when ecology can go beyond the descriptive stage, and studies and analyses the problems numerically, a rapid advance will follow. Dr. B. P. Uvarov said that to him it was very significant that practically all speakers had concentrated their attention on problems of the individual ecology of species, or of groups of species, rather than on community ecology. The way of individual ecological studies may be a long and arduous one, but it is a very healthy symptom that British ecologists are deliberately choosing it instead of the easier, but barren, method of mass collecting, counting and statistical analysis of populations assumed to form communities.

OBITUARIES

Sir David Prain, C.M.G., C.I.E., F.R.S.

THE death of Lieut.-Colonel Sir David Prain on March 16 has removed from the botanical world a distinguished man of science and an endearing personality.

Born at Fettercairn, Kincardineshire, nearly eighty-seven years ago, Prain was a product of the period when recruits to the botanical ranks were mostly obtained from the medical profession. From Aberdeen Grammar School he passed to the University, where he graduated with honours in science, and after an interlude of two years teaching turned to medicine, for which he qualified with distinction in 1882. The two following years were occupied in the positions of demonstrator in anatomy at the Edinburgh College of Surgeons and then at the University of Aberdeen. In 1884 he entered the Indian Medical Service, where his botanical aptitude at once attracted attention, so that at the age of thirty he began an official botanical career as curator of the Herbarium at Calcutta and eight years later became professor of medical botany. Thus the earlier years of Prain's life were largely spent in the art of imparting knowledge to others, but with his appointment as director of the Botanical Survey of India and superintendent of the Calcutta Botanic Garden in 1898, Prain entered on the career of administration in which he achieved such conspicuous success. During this period he not only acquired a considerable knowledge of the Indian flora but also was instrumental in furthering the cultivation of species of medicinal value. In particular the cinchona production of India is almost wholly an outcome of his foresight and initiative.

When in 1903 Sir Francis Younghusband led the Sikkim-Tibet Boundary Commission, Prain accompanied it as botanist and, as a result, our then scanty knowledge of the flora of that area was greatly augmented.

Among the earliest of his more important scientific works was an account of the plants of Bengal which dealt with nearly three thousand species and provided descriptions of all the genera and keys to the individual species. A substantial monograph of the Indian species of Pedicularis, of which sixty-nine were then known, contained an analysis of their distribution, and this was also a feature of the comprehensive account of the genus Dioscorea in four folio volumes which he wrote with I. H. Burkill. His interest in regional botany was again seen in his "Vegetation of the Coco Group" (1891), "The Botany of the Laccadives" (1893), and the "Flora of the Sundribuns" (1893). To Prain also we owe the first authoritative monograph of the genus Meconopsis, which has gained in both botanical and horticultural interest with the passage of time. His contributions to botanical knowledge were recognized by his election in 1905 to the Royal Society, which he served as treasurer for ten years from 1919.

Prain's appointment as director of the Royal Botanic Gardens, Kew, in 1905 was the beginning of seventeen years of efficient control of an institution that had already become by its size, functions and importance the chief taxonomic centre of the British Empire, and where advice was sought on the widest range of botanical interests. Here the new director's many gifts found scope to the benefit of the Gardens themselves and to science in general. His winning and kindly personality coupled with a humour, no less real because it had a subtle Scots quality, endeared him to his colleagues, while even those who might not agree with him could not fail to respect an integrity that was always courteous and just. Many of his minutes, written as director, are models of lucidity and well-chosen phraseology which lost nothing of their trenchant forcefulness by reason of their meticulous correctitude.

No one was in greater demand as a president of societies or conferences, and as a chairman of difficult committees his qualities of sound judgment and firm tolerance were seen at their best. It would be tedious to enumerate the list of important offices he filled, but by reason of his long tenure mention may be made of his service for thirty-four years as chairman of the governors of the John Innes Horticultural Institution, for twenty-seven years as a Carnegie Trustee, and for twenty years as a trustee of the British Museum. He also served for many years as chairman of the Advisory Council for Plant and Animal Products of the Imperial Institute and was director of the Forest Products Research Board, not the least of the services he rendered to the progress of economic botany.

The later years of Prain's life were marred by increasing deafness and, although his mental alertness

was unimpaired, he felt keenly the sense of isolation which this engendered. The extent to which he prized personal contacts can be gauged from a passage in one of his letters, written in 1937: "the tragedy of age, and the only one that hurts is the loss of friends whom one has survived". We too have suffered the loss of a much-valued friend, and science one who served her well. E. J. Salisbury.

Flight-Lieut. J. A. Moy-Thomas

By the death, in a motor accident while on duty, on February 29, of Flight-Lieut. J. A. Moy-Thomas at the age of thirty-five, we have lost one of the most distinguished of the younger generation of zoologists. The study of fossil fishes attracted him most, and he made many valuable contributions to our knowledge of their structure and classification. Particularly did he devote himself to unravelling the difficult problem of the true affinities of certain well-known forms of very obscure relationship.

A pupil of Archer Vassal at Harrow School, he obtained a scholarship at Christ Church, and read honours in both zoology and geology at Oxford. His first published research was on the development and attachment of teeth in fishes (*Quart. J. Roy. Micro. Soc.*, 76; 1934). There followed a series of memoirs on Chondrenchelys, Pristychius, Petrodus and other early shark-like forms, many of which he had collected himself during his expeditions to Scotland and elsewhere. These researches threw much light on the evolution of the Selachii and Bradyodonti including Holocephali. Already, in 1934 (*Proc. Zool. Soc.*), he had pointed out the affinity that very aberrant Palæoniscid, called Tarrasius by Traquair, may have with the living Polypterus (of which he had published a description of the chondrocranium), and thence passed to the detailed study of Palæoniscids in another series of memoirs not yet completely published. In the course of this work he brought out several papers in collaboration with E. I. White, of the British Museum, and Miss Bradley Dyne. With the same admirable powers of observation and happy interpretation he next dealt with the Cœlacanths, and described those of Madagascar. In 1939 he joined an expedition to Greenland to collect material with his intimate friend Prof. E. A. Stensiö of Stockholm.

Particularly important and characteristic of his careful method of dealing with difficult material is Moy-Thomas's work on Palæospondylus, recently published (*Phil. Trans. Roy. Soc.*; 1940). This little fish from the Mid-Devonian of Scotland has been a puzzle to all observers since Traquair first described it in 1890 and assigned it to the Cyclostomes. This interpretation was generally accepted, though some believed it to be a larval form of some higher fish or even amphibian. Moy-Thomas, after examining a vast number of specimens, rejected the larval theory as inconsistent with the presence of well-formed vertebral centra and the condition of the elements of the skull, and also was unable to confirm the presence of many alleged Cyclostome characters. More important still, he discovered that the tail had hitherto been misinterpreted, had been described upside down, and was really heterocercal with a larger ventral lobe supported by jointed radials; he also provided good evidence of the presence of paired fins, and of jaws. Thus he seems to have established that Palæospondylus belongs to the Gnathostomes. Fortunately, the most important results of these various researches were embodied in his excellent little book on "Palæozoic Fishes" (1939), published just before the War.

Deeply interested in the comparison of the dermal bones of the skull in the various groups of Osteichthyes and Tetrapoda and the tracing of their homologies, Moy-Thomas was not content with mere observation and description, but tried by experimental methods practised on living forms to discover the causes which may influence their shape, size and number. Already in 1941 he had reached important results on the rainbow trout, and concluded that, contrary to earlier theories, the origin of such bones is not due to the presence of the sense organs of the lateral line system or of the central nervous system (Nature, May 31, 1941, p. 681).

Moy-Thomas began his teaching career under Prof. W. Garstang at Leeds, where he went soon after taking his degree. Returning to Oxford, he was made University demonstrator and lecturer in the Department of Zoology and Comparative Anatomy in 1933, and also became the first holder of the fellowship founded by the late E. T. Browne at the Queen's College.

Moy-Thomas's love of accuracy and his excellent memory made him a most successful teacher and tutor. But his influence on his pupils was not only academic. Possessed of great gaiety, sense of humour and zest of life, he was a continual source of stimulation and pleasure to everyone who knew him. With these attractive gifts he could make criticism, not only of their work but also of their life and manners, acceptable to his pupils.

Thus by this tragic accident has been cut short the life of one who will be much regretted by colleagues and many friends in Oxford and elsewhere. He leaves behind his wife and two children.

E. S. Goodrich.

Prof. H. Buisson

Henri Buisson, professeur de physique générale à l'Université de Marseille, est mort le 6 Janvier 1944 à l'âge de 70 ans, après une courte maladie. Il s'était fait connaître par de nombreux travaux sur l'optique, souvent avec Charles Fabry (métrologie interférentielle, repères spectroscopiques formant le 'système international des longueurs d'onde', photométrie, 'équivalent mécanique de la lumière', etc.). Depuis 1912, il s'était consacré, avec Fabry, à l'étude de l'ozone atmosphérique, travail qui avait été l'origine de nombreuses recherches, principalement en France (Cabannes, Dufay, Gauzit, Chalonge, Vassy, etc.) et en Angleterre (Dobson et ses collaborateurs).

Ch. Fabry.

The work of MM. Fabry and Buisson on atmospheric ozone was the foundation of all later work on the subject. It had been suggested that the remarkably sudden 'cut off' of the solar spectrum at about 3000 A. was due to absorption in the earth's atmosphere. To test this hypothesis, they made careful measurements of the absorption by ozone of light of different wave-lengths in the laboratory and compared this with the extinction of sunlight passing through the atmosphere. From these measurements they were able to confirm the hypothesis, and also showed that the total amount of ozone in the atmosphere was equivalent to a layer of pure gas about 3 mm. thick.

In addition, Prof. Buisson made regular daily measurements of the amount of ozone in the atmosphere at Marseilles and also showed that the amount of ozone in surface air was relatively very small.

The importance of ozone in the upper atmosphere lies in the fact that, together with carbon dioxide and water vapour, it probably governs the radiative equilibrium temperature at great heights, and is largely responsible for the existence of the upper warm region at a height of 50–70 km., where the temperature is probably above that at ground-level. For these reasons the names of Fabry and Buisson are familiar to meteorologists the world over.

G. M. B. DOBSON.

Dr. E. Granichstadten

DR. E. GRANICHSTADTEN died at Edinburgh on January 5, 1944. He was one of Austria's most successful industrial chemists, possessing the rare ability both to make discoveries and to apply them; he was also a great benefactor to science. His most outstanding contribution to chemistry was the development of the catalytic hydrogenation of oils and fats which made margarine manufacture possible. Shortly after Sabatier and Senderens had demonstrated that unsaturated hydrocarbons in the gaseous phase could be hydrogenated in the presence of a nickel catalyst, Dr. Granichstadten began his experiments on the transformation of vegetable oils into edible fats. After many difficulties he finally succeeded by passing electrolytic hydrogen through the highly purified oils into which the catalyst had been introduced as a readily reducible nickel salt, a process which found wide industrial application in most European countries.

In later years Dr. Granichstadten founded and endowed a research institute at the Alpine spa Gastein with the view of putting the renowned effects of its radioactive springs on a scientific basis. Spectacular progress had been made by the time Austria was invaded. Within three days of the invasion, Dr. Granichstadten was forbidden to enter his own institute, and shortly afterwards he was driven from his native country. He found refuge at Edinburgh, where he was engaged in experiments on nutrition until his premature death.

M. F. PERUTZ.

WE regret to announce the following deaths:

Sir Charles Boys, F.R.S., on March 30, aged eighty-nine.

Sir Cecil Harcourt-Smith, K.C.V.O., formerly keeper of Greek and Roman Antiquities, British Museum, director of the British School at Athens during 1895–97, and director of the Victoria and Albert Museum during 1909–24, on March 27, aged eighty-four.

Sir Thomas Lyle, F.R.S., formerly professor of natural philosophy in the University of Melbourne, aged eighty-three.

Prof. L. R. Wilberforce, professor of physics in the University of Liverpool during 1900–35, on April 1, aged eighty-two.

NEWS and VIEWS

Parliamentary and Scientific Committee

THE annual report for 1943 of the Parliamentary and Scientific Committee refers to a substantial increase in membership. Subjects with which the Committee was concerned during the year included income tax and subscriptions to learned societies, coal utilization research, the training of Civil servants, scientific research and the universities in post-war Britain, on the last three of which reports have been issued, research and Colonial development and income tax and research expenditure, on which a memorandum has since been issued. Further action is projected in regard to the universities and research. A motion has been tabled by members of the Committee in the House of Commons which, it is hoped, may provide the opportunity for a debate during the current session, while a sub-committee has been set up to report on the general question of how research in Great Britain might be developed and organized in the most efficient manner. At the annual general meeting held on February 3, 1944, the chairman reported that it was hoped that the first report would cover a general introduction as to the principles which should be applied to the organization and development of all fields of research work and the development of industrial research. Further reports might concentrate on research and agriculture, research and housing, etc.

At the annual luncheon on the same day, Lord Samuel, after referring to the presence in the Government of four men who had undergone scientific training at the universities, suggested that the Lord President of the Privy Council should have his functions enlarged so that he might become the representative of science as such in the Cabinet and among the other Departments. Lord Woolton paid a warm tribute to the work of the Committee, emphasizing that it is by the application of scientific discovery to the ordinary everyday life of the people that we raise the standard of life of the whole community, and referring particularly to what had been done in recent years with regard to food. Sir Raymond Streat suggested that the immense enlargement of the areas of fundamental knowledge and the increasing tendency for society to demand from science the attainment of specific objectives are leading us into an age of applied research. To meet that challenge, we have not so much to extend the quality and volume of our scientific work as our organization to develop and apply it, and to evolve modifications of our social, political, economic and legislative framework so that we may absorb the impact of an era of research and increase the health and vigour of our society. In connexion with the last, British natural conservatism is our danger. To what extent are our ideas of social security, our instinctive reluctance to acknowledge obsolescence, our regard for property, our trade union practices, inimical to rapid absorption of the consequences of scientific progress? Every effort should be made to prepare the public for the pace at which society must absorb the fruits of scientific work.

The Airborne Surgical Unit

The limited but valuable experience which has been obtained of the feat of taking a surgical team into action with airborne troops is described by two R.A.M.C. surgeons who have organized it, Mr. C. J. Longland and Mr. L. Kessel (*The Lancet*, March 18, 1944, p. 381). Their article has been written "to correct the hyperbole and inaccuracy of accounts which have appeared in the lay press". Such surgical teams have been in action twice. On the first occasion it was proved that the feat could be done; the second job was a difficult one, but the team successfully established itself at night in a farm building behind the enemy's lines while a battle was going on near by. Some of the thirty-five operations performed were done $1\frac{1}{2}$ hours after the wounds were received, and four fifths of them were done within five hours of the wounding. The team consisted of a surgeon, an anæsthetist and five other ranks, one of whom was responsible for resuscitation and two were chosen for their nursing abilities. All were, however, trained in all phases of the work. The team also had field and parachute training.

The details given of the equipment taken will interest all who have to provide transportable surgical equipment for field purposes. It was found that a light operating table or stretchers and trestles can be carried. Anæsthetics, plaster, dressings and other expendable material were put up in packs suitable for ten cases. Other items were instruments, plasma for resuscitation, feeders, bowls, trays and other ward equipment, and a sterilizer and boiled water container into which some materials could be packed. Linen thread was the basic suture material, and acriflavine tablets were found to be the most economical and useful antiseptic. Primus stoves were found satisfactory for heating, provided that several were available; but it was "distressingly and effectively proved" that ether may be a dangerous cause of fire in a theatre heated by primus stoves. Out of 150 cases, only 11 needed any anæsthetic other than pentothal; the other anæsthetic used was chloroform. For lighting, the choice fell on paraffin pressure lamps and electric headlamps.

Apprentice Scholarship Scheme at Birmingham

In his annual report to the court of Governors of the University of Birmingham, the Vice-Chancellor (Dr. Raymond Priestley) comments on education for engineers. The University Joint Recruiting Board has been favourably impressed by engineering apprentices who have appeared before it for deferment or allocation in connexion with the Higher National Certificate in various branches of engineering. These men have entered industry either at or before the School Certificate stage, and have qualified, chiefly through evening work at technical colleges, to pass severe theoretical and practical tests. The successful candidates have impressed those whose duty it has been to interview them by their quality, grit and obvious sense of social responsibility. It has been quite clear that many of them are deserving of, and would be the better for, full-time university education, and that any university would benefit from their presence as students. Through conferences between the University of Birmingham, the Midland technical colleges and local firms, a scheme has been devised whereby the pick of the National Certificate holders in the Midlands might be admitted to the degree courses in mechanical and electrical engineering of the University. Candidates who have been three years in industry and who are nineteen years old or older will be able to matriculate through an examination towards which National Certificate subjects will count. A paper designed mainly to test ability for expression in English is the only additional obstacle to be surmounted. National Certificate scholarships with full maintenance, including residence at a hostel for the three years of the degree course, have been founded already by several firms.

Dr. Priestley points out that if the full value of the apprentice scholarship scheme is to be realized, it is essential that there should be the earliest possible modernization of the engineering equipment at the University of Birmingham. An appeal is therefore being made to the engineering industry of the nation, and particularly that part of it located in the Midlands, for a quarter of a million pounds for new buildings and equipment—a modest request for the Departments of Mechanical and Electrical Engineering. Close co-operation between the university and industry is necessary, and industry must accept the view that the university cannot by itself make practical engineers, production planners, and industrial managers. The university's primary aim must remain, on the research side, original contributions to the science of engineering; on the teaching side, the utmost possible development of the personality of students and a sound grounding in the sciences that underlie engineering and the basic principles of engineering science. What is needed is more and larger faculties of technology in the universities, possibly more universities, not hybrids in which applied science is developed to hypertrophy in dangerous isolation. The Manchester College of Technology is a good example of a well-developed faculty of technology in a university. We need also a more equitable division of Great Britain's intellectual *élite* among the universities.

Scientific Research and Development in India

In his opening address to the symposium on "Post-War Organisation of Scientific Research in India" held at Calcutta during September 27 and 28, 1943 (*Science and Culture*, 9, 135; October 1943), Sir J. C. Ghosh urged that the time is ripe for a critical examination of the facilities for scientific research and training that are available in India, and for drawing up plans for improving and co-ordinating such facilities. At present the agencies responsible for this work are the universities, the central institutes under the Government of India, the Imperial Council of Agricultural Research, the Indian Research Fund Association, the Board of Scientific and Industrial Research, the endowed research institutes like the Indian Institute of Science, the Indian Association for the Cultivation of Science, the Bose Research Institute, etc., and the research laboratories of industrial concerns like the Tata's. Sir J. C. Ghosh suggests an annual grant of Rs. 2.6 crores for research, and an equal grant for training research workers, as reasonable in the first three years after the War. With regard to organization, he suggests that the National Research Council of Canada rather than Russian methods may form the best model for India. Laboratories concerned mainly with short-range programmes of research should be administered by an all-India national research council through properly constituted research committees functioning on their governing bodies. With regard to develop-

ment work, he advocates the formation of a corporation of the type of Research Enterprises Ltd. managed by the National Research Council of Canada. Such a development corporation should be encouraged to take risks by an annual State grant, and introduce into industry and agriculture the inventions and processes worked out under the national research council.

New Light on the Inductive Method

EVERYONE who is interested in the foundations of scientific method will find it worth while to read the article entitled "Hr. Von Wright on the Logic of Induction" which appears in the issue of *Mind* of January 1944, from the pen of Prof. C. D. Broad. It is Prof. Broad's account of the attack on the problem of induction which Hr. Von Wright has made in his published works consisting of a thesis (in English) and an article (in Swedish) on logical subjects. Prof. Broad deserves our thanks for bringing the content of these two works to the attention of English logicians. This article not only presents a remarkable original contribution of the Swedish logician but also reveals Dr. Broad's own illuminating comments upon it. It is impossible to summarize the argument adequately in a few sentences. The article begins by pointing out that *where an unlimited sequence of instances is concerned,* the proposition "100% of the Q's are R's" does not entail the proposition "All the Q's are R's". The nucleus of the problem of induction is, "How can we pass from propositions of the former type based on a finite number of Q's to propositions of the latter type ?" The attempt to justify such a passage by *a priori* argument is neatly refuted by a proof both ingenious and conclusive. The attempt to justify it by arguments *a posteriori* leads to a discussion of how in practice the necessary and/or sufficient conditions of a phenomenon are established. The question then arises: "Can we infer with certainty by such means general propositions about the necessary or sufficient conditions of a given characteristic Q ?" The answer, very briefly, is: "Not without the help of postulates". These postulates are either *a priori* propositions, which is proved impossible, or inductive generalizations, which would lead to a vicious circle. Hence no justification of inductive generalization along these lines is possible.

Radio-Frequency Heating

AT an informal meeting of the Institution of Electrical Engineers held in London on January 24, the industrial applications of radio-frequency methods of heating were discussed, and the opening speaker was Mr. N. R. Bligh. The two main fields of application were eddy current heating and capacitance current heating. A third heating field was where the use of radio-frequency currents was only involved because such currents could be led into the charge through small capacitances; the actual heating process, however, was of the resistance heating class. The valve generator appears to be capable of generating all the power yet required for any application, even up to the highest frequencies of some hundreds of megacycles, and Mr. Bligh suggested that the only power rating which should be stated for a radio-frequency generator is its power output into its optimum resistance load, though for convenience the volt-ampere rating might also be given. The self-oscillator was regarded as the simplest form of generator, and up to a few hundred watts, glass envelope valves could be used, but beyond this external anode valves were preferable.

Regarding the load circuits proper, the charge is placed between condenser plates for capacitance current heating with one side of the load preferably at earth potential. In the case of eddy current heating the heating coil should be as tightly coupled to the charge as mechanical and electrical conditions allow. Applications of capacitance current heating are the completion of the dehydration of food, and the bonding of thin layers of thermoplastic materials such as vinyl resins and the cellulose esters. Eddy current heating has been used for some time in the production of thermionic valves, while the heat treating of surfaces and heating of very small items are becoming increasingly common.

Electricity Supply System Load Analysis

IN a paper read in London on March 16 before the Institution of Electrical Engineers by Mr. P. Schiller, an analysis is presented of the load on the system of the Northmet Power Co. during the year ended June 30, 1939. The block of annual load is split up into a basic or all-the-year-round portion, and a seasonal portion, the latter representing all the consumption due to space heating and about half that due to lighting. The basic portion is sub-divided into its principal components, and for the seasonal portion, an attempt is made to separate lighting load and space-heating load, in respect of both demand and annual consumption. Seasonal demand curves are developed, in which the load at a certain time of day is plotted for a series of days, and compared with the simultaneous conditions of outdoor temperature and illumination. The annual load factors of modern lighting and space-heating loads are found to be normally of equal order of magnitude; in a year with a cold snap the load factor of the latter may even be considerably lower than that of the former. Characteristic collective and component load curves are given, and graphs are presented dealing particularly with the space-heating load. The paper concludes with recommendations for further research.

Electrical Installation Equipment

A PAPER entitled "The Influence of Maintenance Requirements on the Design of Electrical Installation Equipment", read in London on March 9 by Mr. H. Drake before the Institution of Electrical Engineers, points out the weaknesses of electrical installation equipment from the maintenance point of view with particular reference to domestic and commercial installations; in addition, a few comments are given on industrial equipment, the design of which seems far more satisfactory. Wherever possible, improvements and remedies which are commercially practicable are suggested. The equipment has been considered under the headings of switch and control gear, cables and cable accessories, wiring systems and accessories, utilization, including domestic, commercial and agricultural applications, and industrial plant. In general, complaints fall into the four main categories of insufficient space for wiring, inadequate terminal arrangements, lack of standardization and lack of appreciation of the innate clumsiness of the general public. If manufacturers' future designs overcome these four fundamental difficulties, much perplexity will be saved in the maintenance and installation industry.

Agricultural Scholarships

THE Ministry of Agriculture and Fisheries invites applications for ten senior scholarships, tenable at agricultural colleges or university departments of agriculture, for diploma or degree courses in an agricultural subject or at veterinary colleges for courses in veterinary science; and for six extended junior scholarships (for those who have already held junior awards), and thirty junior scholarships, tenable at farm institutes or similar institutions, for courses not exceeding a year in duration, in agriculture, horticulture, dairying or poultry husbandry. The scholarships are open to the sons and daughters of agricultural workmen or of working bailiffs, smallholders and other rural workers whose means and method of livelihood are comparable with those of agricultural workmen, and to persons who are themselves *bona fide* workers in agriculture. The value of the awards is such that neither the recipients nor their parents are normally required to make any contribution towards the cost of training provided. The usual method of selection is by interview, no written examination being held. Further information can be obtained from the Secretary of the Ministry, Block 4, Bickenhall Mansions, Baker Street, London, W.1, or from the offices of County Councils. The latest date for submitting applications is April 30.

Recent Earthquakes

DURING December 1943, twenty-eight earthquakes were registered by the seismographs at the geophysical observatory at Toledo in Spain. The greatest of these occurred on December 1, and registered at 10h. 47m. 14s. from an epicentre some 87·2° distant from Toledo. The depth of focus has been estimated to have been 150 km. and the earthquakes gave rise to amplitudes of 130 μ at Toledo. The nearest earthquake to Toledo during the month occurred on December 31, registering at 19h. 29m. 24s. from an epicentre 240 km. distant. The next nearest occurred on December 26 from an epicentre approximately 470 km. distant. This last epicentre may have been in the Pirineos Centrales.

During December 1943, thirteen strong earthquakes were registered on the seismographs in New Zealand. The following had their epicentres tentatively determined at the Dominion Observatory, Wellington: (1) December 1, New Guinea region; (2) December 2, south of Kermedecs; (3) December 23, New Guinea–Solomons region; (4) December 24, New Guinea–Solomons region (two shocks); (6) December 27, near latitude 36° S., longitude 175° W.; (7) December 30, Kermedecs region. Additionally, twelve earthquakes were reported as felt during the month in New Zealand. The greatest of these was scale V (modified Mercalli) and happened in the neighbourhood of Whangamomona on December 3. This shock was also felt near Taumaranui.

Training for the Chemical Industries

IN an address to the London Section of the British Association of Chemists on March 4, Dr. T. J. Drakeley, principal of the Northern Polytechnic, made a strong plea for a recognized system of technical education in Britain on an equal footing with more academic subjects. He attributed the industrial decline of Great Britain—instanced by the dyestuffs and coke industries—to the lack of such a system of technical training, in contrast to the highly developed system of technical high schools on the Continent, such as those at Delft, Zurich, Stockholm and Charlottenburg. He criticized the report of the Chemistry Education Advisory Board for stipulating that the study of a branch of applied chemistry should always be preceded by a three-year degree course in pure science. He maintained it is impossible to justify the view that the metal chemist and the rubber chemist should have the same basic training. It is only on the basis of a trained personnel that the chemical industries can regain world markets, revive British prestige and pass into a prosperous period of progress.

Royal Society of Edinburgh Awards

THE following awards have been made by the Council of the Royal Society of Edinburgh: Keith Prize for the period 1941–43, to Prof. James Ritchie, professor of natural history, University of Edinburgh, for his papers in the *Proceedings* of the Society within the period of the award and in recognition of his distinguished contributions to natural history; Neill Prize for the period 1941–43, to Dr. Douglas A. Allan, director of Liverpool Public Museums, for his papers on "The Geology of the Highland Border Region", published in the *Transactions* of the Society.

Announcements

THE Council of the Iron and Steel Institute has awarded the Bessemer Gold Medal for 1944 to Mr. Essington Lewis, director-general of munitions and director-general of aircraft production for Australia, formerly of the Broken Hill Proprietary Co., Ltd., in recognition of his outstanding services to the iron and steel industry of Australia.

MR. JOHN G. WINANT, American Ambassador in Great Britain, on March 31 presented the Charles P. Daly Medal and the Cullum Medal of the American Geographical Society to Sir Halford Mackinder, formerly professor of geography in the University of London, and Mr. Arthur R. Hinks, secretary of the Royal Geographical Society, respectively.

PROF. J. M. MACKINTOSH, since 1941 professor of preventive medicine in the University of Glasgow, has been appointed as from October 1 to the University chair of public health tenable at the London School of Hygiene and Tropical Medicine. He was formerly chief medical officer to the Department of Health for Scotland.

SIR AUREL STEIN, who died on October 26, bequeathed his collection of Oriental manuscripts, notebooks of travels, and written papers of a scientific character to the library of the Indian Institute at the University of Oxford, and residue, subject to life interests, to form the Stein-Arnold Fund for exploration of the ancient civilizations of India, China and Iran.

THE following degrees have been conferred by the University of Aberdeen: *D.Sc.*: G. H. Rawcliffe, for a thesis on "Some Current, Voltage and Power Relations for Complex Mercury Arc Rectifiers"; *M.D.*: S. A. B. Black, for a thesis on "The Environmental Health of British Merchant Seamen".

ERRATUM. In NATURE of March 18, p. 351, the price of the report on Polyzoa issued by the Discovery Committee should read 35*s*. net, not 9*d*. net as printed.

Synaptic Transmission in the Spinal Cord

THE preparation used in this investigation has been either the spinal cord of the decerebrated or anæsthetized cat or the isolated oxygenated spinal cord of the frog, and it has been activated by electrical stimulation of a dorsal root (the 7th lumbar or 1st sacral in the cat, the 9th or 10th in the frog).

As Barron and Matthews[1] have shown, a single dorsal root volley normally sets up a large and prolonged negative potential of adjacent ipselateral motoneurones on which are superimposed spike potentials of discharged impulses (cf. ref. 2). The prolonged negative potential differs from the spike potentials in being decrementally transmitted by electrotonus along the axons of the motoneurones, and in the present experiments it has been recorded from the ventral root as it emerges from the spinal cord. This potential has been found to be diminished and shortened by nembutal anæsthesia, and ultimately with deep anæsthesia (about 100 mgm. per kgm. intravenously in the cat or prolonged soaking in 1 in 5,000 in the isolated frog's cord). A dorsal root volley sets up no spikes, but only a simple brief negative potential with a quick rise and a slower, approximately exponential, decay. It spreads electrotonically along the ventral root. The durations of latent period, time to summit, and time of half-decay are about 0·8, 3 and 7 msec. in the cat and 1·5, 5 and 25 msec. in the frog. When the potential is sufficiently large, owing either to a lower depth of anæsthesia or to summation of two or more successive responses, the motoneurones discharge impulses. The potential is thus analogous to the local catelectrotonic potentials set up by trans-synaptic stimulation of curarized ganglia[3] or neuro-muscular junctions[4,5], and may be termed a synaptic potential. Similarly, too, it appears to be set up by a brief active depolarizing agent, its decay being passive and governed by the electric time constant of the membrane.

The brief synaptic potential recorded in deep anæsthesia must be set up in the motoneurones by impulses in those dorsal root fibres which end in direct synaptic contact. By making the anæsthesia deep enough to block all synaptic transmission of impulses, the setting up of internuncial impulses has been prevented, and the spinal cord has been reduced to a single synaptic preparation (the two-neurone reflex arc). The complex and prolonged synaptic potential normally set up in motoneurones by a dorsal root volley results from summation of the synaptic potentials set up by bombardment of the motoneurones by the initial direct volley and later internuncial discharges.

With rapid repetitive stimulation (up to 200 per sec. in frog, 400 per sec. in cat) synaptic potentials in the anæsthetized cord sum to a plateau which decays abruptly on cessation of stimulation. There appears to be no building up of a persistent actively depolarizing agent such as gives the initial slowed decay with synaptic potentials of ganglia[3].

Eserine (intravenous doses up to 1 mgm. per kgm. in cats, prolonged soaking in 1 in 100,000 to 1 in 10,000 in isolated frog's cord) has no appreciable action on the time course of the synaptic potential of the anæsthetized motoneurones (single, double or repetitive stimulation). There is no trace of the prolonged junctional potential which was observed after repetitive trans-synaptic stimulation of the eserinized and curarized muscle or ganglion, and attributed to the accumulation and persistence of acetylcholine[6,7] Dale and co-workers have provided convincing evidence that acetylcholine acts as a synaptic transmitter at such junctions. With synapses in the central nervous system, however, there is no unequivocal evidence of synaptic transmission by acetylcholine, so the present negative results with eserine make it unlikely that acetylcholine plays any part in the synaptic transmission of simple spinal reflexes. On the other hand, the time course of the active depolarizing agent is so brief that it could be due to direct electrical stimulation of the motoneurones by the action currents of impulses in the terminals of the dorsal root fibres. Similarly, it was suggested[7] that the analogous brief transmitter action observed in sympathetic ganglia was possibly due to a direct electrical action, but with ganglia it is superimposed on the more prolonged depolarization due to acetylcholine transmission.

Synaptic transmission in the spinal cord is also different from that in muscle and ganglia in that it is not paralysed by curarine. In fact, curarine has the reverse effect, having a mild strychnine-like action in concentrations so low as 12 μmol. per litre.

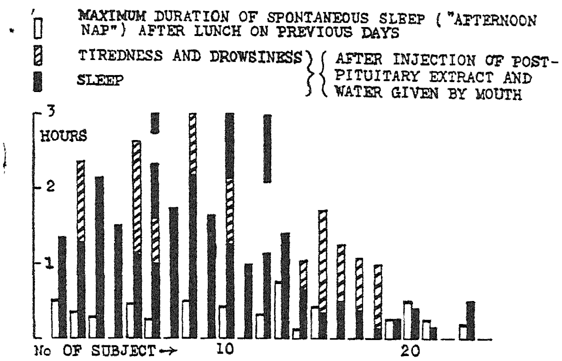
Induction of Sleep by Simultaneous Administration of Posterior Pituitary Extracts and Water

THE following investigation arose from considerations based upon well-known observations on the state of normal sleep. These are: (*a*) that during sleep the urine volume output is decreased and the blood diluted; (*b*) that many drugs (caffeine, etc.) which cause wakefulness are diuretics; and (*c*) that severe muscular work which, it is recognized, often facilitates the onset of sleep, has an antidiuretic action. It was thought, therefore, that the antidiuretic principle of the posterior pituitary, if given together with water, might possibly bring about an internal milieu so similar in many ways to that of normal sleep (for example, antidiuresis, dilution of the blood) that this state might eventually cause, deepen or prolong natural sleep.

Experiments were made on a number of subjects, many of whom were unaware of the object of the procedure, and were carried out after the average time had been recorded for which each subject would sleep spontaneously after lunch when good and repeatable conditions were given. Through the kind permission of Prof. P. C. Cloake and other clinicians, a number of these experiments were made on suitable hospital patients. Other experiments were made on students where, though the element of suggestion



could not be excluded entirely, some sham injections with saline gave negative results and thus offered a certain measure of control.

Nearly all experiments using 5–10 units of the pressor principle gave negative results, though the antidiuretic effect was, of course, marked. Some effects of these preparations (for example, peripheral vasoconstriction, eventual rise in blood pressure) were thought to be incompatible with normal sleep, where the blood pressure is relatively low. Oxytocic preparations were therefore tried and eventually it was found that 10–15 units of oxytocic preparations, still showing definite antidiuretic action, given together with 1–2·5 units of the pressor principle and 1½–2 pints of water (given orally), had obvious effects. These doses were split into two injections, usually given at 11 a.m. and 12 (noon), and were followed by the subject having a normal lunch. From 2 p.m. the subjects were kept in bed. From the accompanying figure it can be seen that of twenty-four cases treated in this way thirteen slept for long periods, five cases experienced drowsiness and tiredness, but without sleeping much longer than usual, and six cases gave quite negative results. An additional eleven subjects were treated in slightly different ways (1 per cent saline given instead of water, etc.). Of the total of thirty-five subjects (including those shown in the figure) eighteen slept longer than could be expected normally, eight exhibited symptoms of pronounced drowsiness, while nine felt no effects whatsoever. Symptoms like "the eyes feeling heavy and itching", prolonged yawning, etc., were often recorded. The symptoms never appeared until 2–3 hours after the last injection. The sleep was often very deep and dreamless, which was noted by those who usually dream. It seemed that women responded better than men ; thus of the nine negative cases seven were men. Some subjects mentioned spontaneously a pronounced well-being after the induced sleep. If the injections or the water were given alone, uncertain or negative results were obtained in eight cases.

Whether the described effect is due to the antidiuretic principle, or to the oxytocic one, or to both, cannot yet be stated. It may be that by creating much of the internal milieu of natural sleep, once that milieu is established, sleep may follow as a conditioned reflex, and that the actual chain of events at the normal onset of sleep may be different. The important fact, however, that most of the changes in composition and volume of the blood known to occur during sleep in man develop after merely lying down for 20–30 minutes[1,2] may suggest that the 'water shift' is among the earliest events concerned with the onset and maintenance of sleep, and that therefore the above described effect may not differ essentially from what happens at the onset of normal sleep.

X-Ray Divergent-Beam Photography as a Test of Crystal Perfection

In a recent communication[1] I reported that good type I diamonds gave bad divergent-beam photographs, the deficiency (absorption) lines being scarcely, if at all, visible against a foggy background, whereas type II diamonds gave excellent divergent-beam photographs. I suggested that this could be explained if the type I diamonds were 'ideal' and type II diamonds 'mosaic' in structure. The poor photographs would be an indication of large primary extinction.

Confirmation of this interpretation has come in other ways. Prof. E. N. da C. Andrade tells me that when he and Sir E. (afterwards Lord) Rutherford took the first divergent-beam photographs some thirty years ago, using the γ-rays of radium, they found that a particular ordinary cleavage plate of rock-salt gave moderately good absorption lines[2]. Specimens apparently much more perfect, as judged by specular reflexions of ordinary light, which were selected from a large number specially fetched from a salt mine, gave much inferior effects.

I said also in my communication that crystals of organic compounds gave good photographs. This was true of the substances I had then examined. Further experiment has, however, revealed some notable exceptions. Three out of five crystals of oxalic acid dihydrate gave either no visible lines or lines so faint as to be seen only with the greatest difficulty ; the fourth gave a picture of moderate contrast and the fifth an excellent one. Very poor photographs were given also by erythritol, ammonium oxalate, stilbene, hexamethylene tetramine and a thin cleavage plate of calcite. Sucrose, mannitol, tolane, *trans*-azobenzene, 1-3-5 triphenylbenzene, penta-erythritol and penta-erythrital tetraphenylether gave lines of only moderate visibility. Anthracene, benzil, dibenzyl, benzophenone, maleic acid, maleic anhydride, succinic acid, α-resorcinol, urea nitrate, hexamethylbenzene and hexaethylbenzene gave good clear pictures, although even among these some were distinctly better than others. Only one or two crystals of each of these substances were examined, and the results, therefore, must not necessarily be accepted as typical of the compounds in question. They are given to show what wide variations may exist.

In order to find out whether the absence, or comparative indistinctness, of absorption lines did, in fact, indicate the approach of the crystal to an 'ideal' state, with its resulting primary extinction effect, I dipped two of the oxalic acid dihydrate crystals into liquid air for a few seconds and rephotographed them when they had regained room temperature. The result was that a pattern appeared where none had been seen previously. A second immersion improved the sharpness and visibility of the absorption

lines, although they did not become quite so good as those of the naturally 'mosaic' specimen. The crystals became very brittle; presumably the small-scale breaking-up of the structure into slightly disorientated crystallites (which for complete absence of primary extinction would have to be about 1 μ or less in linear dimensions) was accompanied by cracks on a very much larger scale. Erythritol, stilbene and hexamethylene tetramine also gave good pictures after immersion in, or spraying with, liquid air, and some of the moderately good specimens (sucrose, mannitol and *trans*-azobenzene were tested) gave much improved pictures after similar treatment. Type I diamond and calcite, however, were apparently not affected even by repeated coolings. Those crystals the structure of which had been broken down into a mosaic by sudden cooling continued to give a good divergent-beam photograph even after an interval of more than 100 hours; there was no evidence of any recrystallization.

It is clear that, when X-ray structure analysis is being carried out, the possibility of large primary extinction effects existing even in small crystals of so-called 'soft' organic compounds must not be ruled out of consideration. That some primary extinction takes place in crystals of less than 0·1 mgm. weight was indicated by B. W. Robinson's comparison of the structure factors of anthracene deduced from single crystals[3] and from a fine powder[4], using copper and molybdenum monochromatized radiations in each case. Other workers[5,6] have reported marked primary extinction in single crystals of hexamethylene tetramine, which was reduced by liquid air treatment or eliminated by the use of a fine powder. In spite of these warnings, however, primary extinction has on the whole been neglected in recent years, partly because of the obvious difficulties of allowing for it. My experiments seem to show that some technique of detection and elimination will be essential in all X-ray analytical work where accuracy is desired. If such a technique is not adopted, there is no point in using very accurate methods of intensity measurement.

Large-scale distortion of crystals is readily detected by the divergent-beam method. Several diamonds gave photographs in which there was a general blurring of the lines in one particular direction, or in which lines were doubled which should have been single. It is a simple matter to calculate, from the photographs, the amount and direction of disorientation of individual crystallites necessary to give these effects.

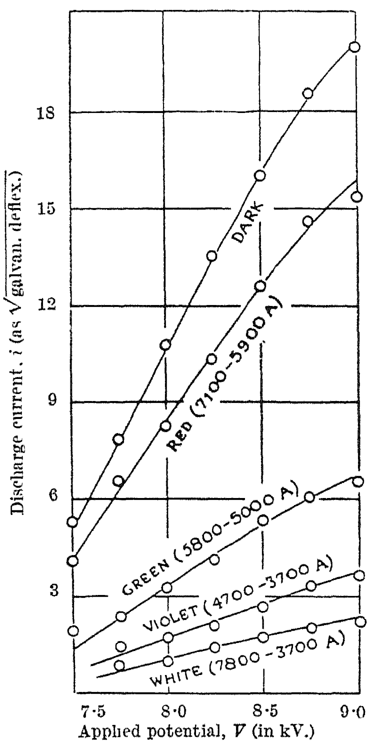
Light-Effect in Chlorine under Electrical Discharge: Influence of the Gas Pressure

AMONG numerous factors which determine the magnitude of the diminution Δi on irradiation of the discharge current i[1–6], the gas pressure p has been found to have a marked influence. The rectifier type A.C. indicator used previously[3] was replaced by a Cambridge vacuo-junction; this increased appreciably the sensitivity of the arrangement, since the corresponding galvanometer deflexions are proportional to i^2.

The characteristic curves in the accompanying graph refer to a discharge produced in a Siemens' ozonizer B, the applied potential V varying over the range 7–12 kilovolts (r.m.s.) at 50 cycles frequency, (i) in the dark, (ii) under irradiation from four 200-watt bulbs run at 180 volts, with a water-filter to minimize the heat effect; and with (iii) violet, (iv) green, and (v) red filters added to (ii). Using the water-filter, the relative intensities observed with a thermopile were: white (100), red (40·6), violet (16·7) and green (1·5); the transmission limits (see graph) were found from spectra taken with a Fuess' glass instrument. At $p = 0·8$ cm. mercury, Δi was not detected despite large variations of V. At $p = 59·6$ cm., Δi for (ii) white, rose from 13 to 35 per cent of i in the dark as V was increased from 9·3 to 11·2 kV.; at high applied potentials the discharge was unsteady; and also Δi was smaller and irregular. The light-effect was a maximum at 46·5 cm.



The intensity in the violet region (4700–3700 A.), especially towards its short-wave end in (ii) unfiltered white, was much greater than in (iii) the filtered violet. As Δi increases in the order, red < green < violet < white, which is different from their relative intensities, the frequency is the major determinant of this phenomenon. That, compared with the green and red, (ii) white and (iii) its violet component contain a much greater part of 2300–5000 A., the chief absorption band of chlorine[7], is possibly an additional factor[3,5,6]. The accompanying curve shows that Δi increases with V and that this influence increases in the order red < green < violet < white. This agrees with our results at various pressures. Further work has shown that $\Delta i/i$ is a more regular function of i than the corresponding V. The precise nature of any of these $\Delta i/i - i$ curves, however, depends

markedly on the pressure. This relation is simple at 46·5 cm.; approximately, $\Delta i/i$ is a constant, dependent upon the light-band.

At this pressure, it was interesting to observe, for example, at 9·0 kV. that, in the dark, i gave a deflexion of 400 units; under (ii) white, it was reduced to 2; corresponding to a light-effect of about 93 per cent. This, together with the fact that it has been observed in some compound and elementary gases, with the exception so far of the rare gases and metallic vapours, indicate a hitherto unrecognized and fairly widespread factor in the electrical discharge and photo-electric phenomena.

An Interferometric Procedure for the Examination of Crystal Surfaces

IN a recent communication[1], Dr. S. Tolansky has described an interferometric method for the study of crystal surfaces. He includes two pictures showing the surface structures of mica and selenite.

This method has been used to great advantage in our laboratories for several years, especially for selecting suitable crystals for X-ray crystallography. In a paper[2] published in the proceedings of the Swedish Academy of Sciences for 1933, some fifty pictures from different crystals, calcite, topaz, quartz, gypsum, mica, rock-salt, sylvine and carborundum were reproduced. All these crystals, even the most perfect ones, gave contour patterns of the cleavage faces showing that the surfaces were split up into a great number of regions with different heights. In calcite, for example, the steps were of the order $0 \cdot 1\ \mu$ and less. It was mentioned in the paper that the method made it possible to measure the steps with an accuracy of 5 A.

MANNE SIEGBAHN.

[2] Siegbahn, Manne, *Ark. f. Mat., Astr. o. Fysik.*, **23**, A, No 12 (1933).

PROF. SIEGBAHN has very kindly sent me a reprint of his paper referred to in his letter; the journal in which it appeared is not available here and I was completely unaware of the existence of the paper.

I cannot agree, however, with Prof. Siegbahn's implication that his method and mine are the same. They are, in fact, very different optical procedures, since Prof. Siegbahn employs the classical *two* interfering beams, whereas I make use of the far more powerful *multiple-beam* interference. As a result of this the resolution in the two cases is of a different order. One can consider as an analogy that his resolution is to mine as the resolving power of a 2-line grating is to that of a 40-line grating. The intensity distributions within the two types of fringes are so fundamentally different that the multiple-beam procedure gives an accuracy of an entirely higher order.

While both methods reveal the coarser details of crystal surfaces equally well (and Prof. Siegbahn's paper contains many beautiful reproductions of fringes revealing coarser details), yet the more precise multiple-beam procedure reveals in addition subtle fine structure details far beyond the possibility of the simpler two-beam method. This difference is entirely a question of fringe width, and the employment of very high reflecting coefficients in my method is responsible for the improvement.

Prof. Siegbahn states in his paper that when his fringes are measured with a photometer, their *positions* can be determined to within 1/500 of an order (despite the very unfavourable $\sin^2$-intensity distribution). This is only 5 A. It is, of course, quite evident that the smallest *step* which he can resolve is much greater than this figure, which is the error in setting on a fringe. With my method, I can readily measure directly (without a microphotometer) actual steps so small as 30 A. in height with an accuracy of 1 A. It is more than probable that with a microphotometer this would be reduced by a factor of 2. Such *resolution* simply cannot be approached with fringes produced by two interfering beams, hence the two procedures cannot be considered equivalent.

While, therefore, the two-beam method is quite sufficiently sensitive for the purpose of selecting suitable crystals for X-ray crystallography, as a method of high precision for revealing the fine structure topographical details of crystal surfaces, it cannot compare with the multiple-beam procedure that I have independently developed. This is perhaps most clearly revealed in a more recent publication of mine[1].

Metabolism of Acetoacetic Acid

IN a recent publication Breusch[1] has reported experiments suggesting a condensation of the $-CH_2.COOH$ group of β-ketonic acids with oxaloacetic acid, resulting in the formation of citric acid.

Shortly after the theory of the citric acid cycle was first put forward by Krebs and Johnson[2], and following the observation of Korányi and Szent-Györgyi of the antiketogenic effect of succinic acid[3], I performed a number of experiments designed to test this very hypothesis. Acetoacetic acid was incubated with slices of rat brain and kidney with and without the addition of various members of the citric acid cycle. The observed effects on oxygen uptake, formation of citric acid and disappearance of total acetone bodies were, however, so small as to be inconclusive. The theory was abandoned on the strength of the following experiment in which the anaerobic disappearance of total acetone bodies was measured by a modified Messinger titration[4,5].

TISSUE INCUBATED FOR 2 HR. IN BICARBONATE-RINGER (N_2/5% CO_2).

Tissue	mgm dry weight	Substrate	Q Aceto-acet.	$Q\beta$-Hydr-oxybutyr.
Rat brain	15 29	acetoacet. (0·002 M.)	—0·49	0·23
	19 92	,, + oxaloacet (0 0067 M.)	—0 55	0 37
Rat testis	33·62	acetoacet. (0·002 M.)	—0·98	0·38
	44 39	,, + oxaloacet. (0·0067 M.)	—0 69	0 35
Rat kidney	14·39	acetoacet. (0·002 M.)	—1·57	0 81
	9·76	,, + oxaloacet. (0·0067 M.)	—1·64	0·85

The reaction acetoacetic acid + oxaloacetic acid → citric acid + H_2O does not require oxygen. According to Breusch[1], the enzyme is insensitive to cyanide. One would have expected, therefore, that addition of oxaloacetic acid would raise the anaerobic rate of acetoacetic acid disappearance to the level of the aerobic rate (Q-value of about 6 for kidney and about 2 for brain). The addition of oxaloacetic acid was, however, without effect.

Moreover, it was found in these experiments that the ratio of acetoacetic acid disappearing to β-hydroxybutyric acid formed was roughly 2 : 1, a result typical for a dismutation, and it was concluded that the first step of acetoacetic acid metabolism is oxidative, or at least reversibly linked with an oxidative step. This, too, was not in agreement with a mechanism where the first step would have been a non-oxidative condensation. Subsequent investigations[5,6] gave no evidence for oxidation at the α- or the γ-position or for an oxidative cleavage into two C_2-compounds.

Though the limited value of negative evidence is fully realized, it remains to be explained why the expected results were not observed under the conditions employed.

Effect of Temperature on the Reducing Activity of Leucocytes in Milk

SOME investigations were carried out as to the possibility of milk from cows infected with mastitis having an increased reducing activity due to the number of leucocytes contained in it, and in consequence failing the Standard Routine Resazurin Test adopted by the Ministry of Agriculture for the grading of milk under the National Milk Testing and Advisory Scheme. During the course of this work, milk samples with a high leucocyte content were submitted to ten-minute and one-hour resazurin tests at 37° C. immediately after production, and then again after holding the milk overnight at different temperatures, so as to attempt to reproduce the varying atmospheric temperatures at which milk is held before testing.

As will be seen from the accompanying results, milk held at 55° F. overnight did not reduce resazurin so rapidly as when tested immediately after production. This is no doubt due to the fact that leucocytic metabolism in milk is entirely catabolic and not anabolic ;

VARIATION IN THE RATE OF REDUCTION OF RESAZURIN DUE TO HOLDING THE MILK AT DIFFERENT TEMPERATURES.

	Resazurin disk reading at the end of		Complete reduction of resazurin
	10 min	1 hour	
Tested immediately after production	4	0	1 hr
Tested after holding at 55° F. overnight	4½	1½	1½ hr.
Tested after holding at 40° F. overnight	0	0	10 min.
Tested after holding at 32° F. overnight	2½	1	1½ hr

for this reason the life of the leucocytes in milk is probably dependent upon the temperature at which the milk is held, and the nearer the temperature is to body temperature the shorter the life of the leucocytes, and the lower the temperature (providing that it is now low enough actually to damage the cells physically) the longer the life of the leucocytes.

If this is so, milk with a high leucocyte content should not reduce resazurin so rapidly after it has been held at temperatures approaching body temperature, and milk held at lower temperatures should reduce at approximately the same rate before and after holding. This has been found to be so, except in the case of milk held overnight at 40° F., when the reducing activity of the cells appear to be definitely increased for no apparent reason.

In all cases a bacterial plate count test was carried out to ensure that any increase in reducing activity was not due to the growth of cryophilic bacteria in the milk during the holding period.

The Soil as a Source of Infection of Dry Rot of Potato

IT has long been suspected that the fungus causing dry rot (*Fusarium caeruleum*) is present in field soils[1,2] and in soil adhering to seed tubers[3], but, so far as I am aware, no direct proof, based on experimental evidence, has been published.

In 1942, inoculation of susceptible tubers with unsterilized field soil, previously sprayed with a spore suspension of *F. caeruleum*, caused dry rot to develop. The result suggested that this direct inoculation method with soil might be useful to prove the presence of the fungus in field soils and in soil adhering to seed potatoes.

In 1942 and 1943, soil samples were obtained from several farms in Cheshire ; each sample consisted of soil scraped from thirty tubers with a sterile knife and collected in a new envelope in the field at digging time, before the tubers came into contact with any possible source of infection such as hampers, seed boxes or sacks. All the samples proved to be infected. Suitable controls remained sound. Similar results were obtained with many samples collected at random from healthy seed tubers stored in seed boxes in lofts during the winter 1942–43.

During the present winter soil samples were collected at wholesale merchants' stores from seed potatoes imported from Scotland and from Northern Ireland. From each consignment ten of the top-

most tubers were taken from each of three sacks; sacks seen to contain diseased tubers (there were very few of these) were not sampled. Of forty-two samples tested (thirty-three from Northern Ireland and nine from Scotland) thirty-seven were infected.

In the above work, re-isolations and re-inoculations were made frequently; the Fusarium sp. isolated have not yet been identified, but all of them produced dry rot when inoculated into test tubers. The *p*H value of the infected soil samples ranged from 5·16 to 6·74.

The results establish that the fungus (or fungi) causing dry rot of the potato is frequently present in field soils in Cheshire and in soil adhering to imported seed tubers before these are distributed to farmers. To prove that field soils in Scotland and Northern Ireland are infected (as is suggested by these results), it would be necessary to collect the samples in the field at digging time.

The method is being used to test loft sweepings and soil adhering to tubers before and after seed treatment with organo-mercury preparations.

The implications of these findings will be discussed in a later publication.

Training for Citizenship

As one who has learned to look to science for a more dependable kind of guidance, I suffered a feeling of disappointment while reading the article entitled "Training for Citizenship"[1].

The deprecation of the omission of any reference to the value of science as a social discipline is mentioned; but the absence of a scientific approach to the problems of education is ignored.

The creed of 'world-citizenship' is applauded. "If we are all good citizens all the other good things will follow." Such an utterance sounds suspiciously like the very dogma of religious belief that science has struggled for centuries to supersede. Surely there is sufficient evidence of relationship between biological knowledge and educational problems for a scientific approach to be made.

Prof. Julian Huxley describes evolutionary progress as "increased control over and independence of the environment. As an alternative we might define it as a raising of the upper level of all-round functional efficiency and of harmony of internal adjustment"[2].

It does not appear illogical or impracticable to interpret this progress into terms of everyday productive and cultural behaviour of individuals. Neither does it appear unscientific to assert that there can be no fundamental difference between the impetus directing the behaviour of an individual and that of the species to which the individual belongs. If this be sound, then the purpose of education may be accepted to be the imparting of knowledge to aid individuals to solve the problems they may meet in their everyday life in a manner which conforms, so far as is practically possible, to the needs of society as an organic whole. The scientific approach is to gather data from the field of everyday behaviour and, in the light of biological and sociological knowledge, define the problems arising from conflict between inner impulses and environmental conditions. After an adequate definition is formed, the hypotheses of education and citizenship may be framed.

The too-academic man of science appears to overlook the fact that most human problems are social and economic in character. Science has already provided methods of dealing with mathematical problems. It is possible for an individual with an elementary school education to solve everyday problems of numbers with his knowledge of arithmetic. It is possible for him to develop his ability to deal with more complex problems of the same sort from the knowledge made available to him by science in a completely progressive manner. A similar facility exists, through the technical levels, in all branches of the physical sciences.

No such progressive ladders are provided by science in the fields of sociology and economics. If they are, the rungs begin too high. We must bear this condition in mind when scientific efforts are devoted to creating conditions of efficient education and 'world-citizenship'.

It must be remembered that types of education already exist and some have existed for many generations for nine-tenths of our population in the forms of newspapers, cinemas, magazines, music-halls, radio, advertising, foremen, salesmen, policemen, etc. (Some of them are applied far more scientifically than the types recommended in NATURE, and are, therefore, more successful in their results.)

Although these types of education lead to commercial and other solutions in accordance with the interests of small groups instead of cultural solutions in accordance with the interests of democratic society, the fact remains they are the sources of instruction received and the directing-forces of everyday behaviour.

Sufficient evidence can be found among sociological data to indicate that individuals do not integrate with groups, or small groups with wider groups, unless an anticipation exists that the consequences will lead to an all-round independence of environment.

The problem confronting the social scientific worker is to explain how individual independence of environment can only increase with an increasing interdependence on the social environment. The next problem—a technical one—is to make it happen.

Unfortunately, for a large number of people the benefits of socialization are not converted into individual advantage. Sometimes it results in a loss. To expect co-operation from individuals whose experience proves it to be detrimental to their conditions of living and to expect them to become conscious of the need for world-citizenship without evidence different from that derived through their common sense is as unscientific an assumption that can possibly be made. It is contradictory to all scientific knowledge.

While the conflict between inner urge and material environment continues, and while a scientifically directed form of government (which must include education up to the world-citizenship level) fails to materialize due to a false approach, then the practical consequences are likely to be of an explosive character that will force a more natural direction.

THE OAK TREE

By ALEXANDER L. HOWARD

"*Stabat in his ingens annoso robore quercus; una nemus.*" (In aged majesty a mighty oak towers o'er the subject trees, itself a grove.)—OVID.

FROM earliest times the oak tree has been held sacred by all people in all countries, and it is not surprising that it was worshipped by the rude and savage barbarians who inhabited Great Britain two thousand years ago, when Druids held their services under their sacred oaks. In comparison to their ignorant and primitive forms of worship it is good to think that these wild people were impressed by the solemn beauty of their great forests, where tall trunks of trees, roofed in with foliage, made natural cathedrals in the open air.

Apart from its beauty and grandeur the oak tree has played a vital part in the growth of our great Empire; in the reign of Queen Elizabeth our small battleships were built almost entirely of oak.

Boulger quotes it as having been the favourite timber of Greeks, Romans, and Norsemen—the latter having used it for the bulding of their long ships. He also tells us how the great iron industry of Sussex, which supplied the cannon for Elizabeth's Navy, relied for smelting upon an inexhaustible supply of British oak.

During the War of 1914–18, at a time of crisis, when foreign supplies of timber failed, the nation once again depended upon the faithful services of this mighty tree.

In a tree song which he dates A.D. 1200, Kipling says:

> England shall bide till judgment tide,
> By oak, and ash, and thorn.

Yet now that we have become in many respects a cultured and enlightened nation, there are ominous signs that the immense value and importance of the oak tree has been forgotten.

Those of us who have seen the great oaks that have been felled during the last twenty years cannot fail to have observed that there were definitely three outstanding plantings: the first, and most important, probably being self-sown, and dating back approximately twelve to fifteen hundred years; the second can be placed about 1450; and the third about 200–250 years ago. On the grassy bank beneath the church at Northiam, Sussex, can be seen two interesting examples—a venerable giant of the earlier date, and slightly lower down the bank a lesser giant, which probably belongs to the second era. Still lower there is a healthy youngster of about forty years, which, however, has been identified as a fine specimen of *Q. Merbeckii*, a semi-evergreen oak, native of northern Africa, which retains its leaves until the New Year. The Knightwood oak, near Lyndhurst, in the New Forest, still stands; until a year or two ago "The Twelve Apostles", in Lord Petre's Park, at Brentwood, Essex, and many other veterans were still flourishing. On Sir George Courthope's estate at Whiligh, near Tunbridge Wells, is an oak tree which can be best described in his own words:

> "the old manorial map which showed a little picture of 'ye olde oake' in more or less its present condition, was dated 1493. The bark is most vigorous. When I was a child there was an opening over two feet wide into the hollow trunk, in which several persons could sit. The opening is now only a few inches wide."

Near by is another fine example, the age of which is unknown, but which I thought might belong to the second category of about 450 years ago. Sir George Courthope describes it as follows:

> "The specimen oak today has a girth of exactly 15 feet five feet from the ground, and is practically cylindrical until the spring of the first two branches, just over thirty feet up. The stem continues from another 10 or 12 feet to the main spring of boughs. It still grows. In, I think, 1920, when the Royal Arboricultural Society first came here, Henry Elwes and Dr. Henry saw the tree for the first time. The girth was then just under 14 feet, and the volume of the log was calculated at 410 cubic feet. In 1914 a would-be buyer . . . offered me £317 f.o.v. . . . for the log up to the second spring of boughs, which they calculated at 634 cubic feet. The haulage of so great a log would have destroyed three-quarters of a mile of farm road and half a mile of carriage drive; so the tree still stands."

It would appear from Sir George Courthope's records that two other somewhat similar trees were taken from the west side of the house and used for the restoration of the Westminster Hall roof. The Clerk of Works to the House of Commons counted more than five hundred annual rings in a squared beam (heartwood only) which was used for this purpose. About thirty years ago another specimen belonging to this category was felled at Danbury Palace, in Essex. This is referred to in "A Manual of the Timbers of the World":

> "it had five secondary trunks growing out of the butt, all of which were of a very rich brown colour. After the tree was sold a man was idly pulling out the decayed wood from a hollow in the side of the trunk, when he felt something hard, which he discovered was a small coin, afterwards found to be of Roman origin."

The authority H. J. Elwes was sceptical about these accounts of the great age of the oak tree—a doubt shared by Sir Geoffrey Evans—but as a result of years of careful study, despite the opinion of these two authorities, I still believe in them. Under the best conditions I think the oak continues to flourish for about five hundred years: apparently a further span of two hundred years follows, during which time little change is noticeable, and afterwards five hundred years or more will be passed before it reaches its last stage. A good example of this later condition can now be seen by the church at Hawkhurst, in Kent, where there is an old oak, its life finished, but the dead remains bricked in. One other, which is still producing a few shoots, can be seen by the church at Catsfield, in Sussex. The historic oak tree at Hatfield Park, now a hollow shell filled with concrete and fenced around (said to have been dead for about sixty-five years) can still be seen. According to tradition, it was under this tree that Queen Elizabeth was resting when she received the news of the death of her sister—Queen Mary. Every care has been taken to preserve it, and there is a tablet painted stating that it is the identical tree. There is every reason to accept this story, and if such be the case we may well believe that four hundred years ago the tree was flourishing, and it is likely that at that time it would have been more than 500–600 years old. In the near neighbourhood, at Brocket Park, a tree still stands, which produces a good crop of leaves year by year. This tree is taken care of and valued for its antiquity. The butt, measuring 32 feet in circumference, is clothed with sound healthy bark to a height of 12 feet, where it breaks out with immense limbs, which still produce an abundance of

rich green leaves. It has sometimes been claimed that it was under this tree that Queen Elizabeth received the news, but the history of Hatfield Park negatives the claim of Brocket Park.

Fifteen hundred years ago Pliny tells us :

"In the same North climate is the mightie forrest Hercynia. A huge and large wood this is, stored with tall and big okes, that never to this day were topt or lopt. It is supposed they have beene ever since the creation of the world, and in regard of their eternall immortalite surmounting all miracles besides whatsoever. And to let passe all other reports which happily would be thought incredible, this is knowne for certaine, that the roots of the trees there, run and spread so farre within the ground, that they encounter and meet one another: in which resistance they swell and rise upward, yea, and raise up mounts of earth with them to a good height in many places: or, where as the earth followeth not, a man shall see the bare roots embowed arch-wise, and mounting aloft as high as the very boughes: which roots are so interlaced, or else rub one against the other, striving (as it were) not to give place, that they make a shew of great portailes or gates standing open so wide, that a whole troupe or squadron of horsemen may ride upright under them in ordinance of battell."

For near 250 years the planting and conservation of the oak tree has almost ceased, and during this critical time prodigious demands have nearly destroyed the last reserves in Britain. Nor is this the worst. Before the War, the numerous country sawmills found it a profitable business to handle small and immature trees, because the plant at their disposal was unsuited for the larger sizes. Meeting a vigorous demand caused by the ever-increasing building operations which have continued since the War of 1914–18, and finding owners hard put to it for death duties and increased taxation, great numbers of oak trees of 60–150 years growth have been reluctantly sacrificed. Indeed, since the present War began, whole tracts of beautiful woodlands have been ruthlessly cut down, quite regardless of size and age, and a host of parks throughout the country have been denuded of timber-like trees.

At three successive periods of our history, the Government or the reigning monarch has recognized the urgency of the situation, so that in the reign of Edward I, again in Elizabeth's time, and lastly in Charles II and James II reigns, laws were passed prohibiting the felling of trees. We read of how Samuel Pepys was greatly troubled on account of a strange situation concerning the Duke of Albemarle and the Earl of Clarendon with regard to the oak trees in Clarendon Park. Pepys notes in his Diary on July 23, 1664, that he would "rather fling away the gains of £2,000 or £3,000, than have it said that the timber *which should have been the King's* . . . was concealed by us in favour of my Lord Chancellor". It would be well if the same spirit which animated the people of those days could be revived again to-day. The fierce flame which burnt in those stormy times is illustrated by the action of the Duchess of Monmouth, who took revenge on King James after her husband had been beheaded, by cutting in half all her oak trees at Moor Park, in order that the timber should not be employed in the building of the King's ships.

The debate in Parliament (1943) possibly marked the second occasion only in more than a hundred years, when this subject of such vital importance to the State received the attention of the Government. One fact alone which emerged should open many eyes, and that is that the soil and climate of Britain can and will produce a growth of forest wealth as good and better than any other country of similar character.

It would, of course, be ridiculous to plant the oak tree in uncongenial areas ; but it should be planted, and planted again continuously, in those soils and counties where it flourishes. Natural regeneration of oaks occurs year after year, and trees so produced have a sturdier and better growth than anything that can be planted. Such areas should be preserved by law, as they have been for years past in southern Europe and elsewhere. No person or municipality should be allowed to cut down any tree, either mature or immature, unless he can prove to the recognized authority that he has planted at least five to take its place, or alternatively, that he has wired against vermin and preserved a naturally regenerated area of equal value.

Elwes mentions in "Timbers of Great Britain and Ireland" innumerable species of oak (*Quercus* sp.) as established in Great Britain, but in this article I shall confine myself to four which I consider the most important, namely, *Q. pedunculata* Ehrh. ; *Q. sessiliflora*, Salisbury ; *Q. Cerris*, Linn. ; *Q. Lucombeana* (Sweet).

Q. pedunculata is represented by many thousands of trees in all parts of England, Wales and Ireland, and in a smaller degree in Scotland. These trees are of all ages, sizes, and in all conditions, but alarmingly reduced in number throughout the last 50–70 years. To-day *Q. sessiliflora* is rare, and a careful search and inquiry carried out during the last forty years convinces me that it has never been abundant in Great Britain. Mr. D. W. Young, the deputy surveyor of the New Forest, tells me that there are considerable tracts in certain parts, but I and many others who have sought for them have never been successful in our search, and I think this species has been introduced from the Continent, an opinion which is shared by others. In beauty as well as in timber, despite the controversy which has persisted since the time of wooden ships and the writings of Laslett, we can safely say that these first two species have equal merit.

In strength and durability there is nothing grown in our country which can compare with British oak, and indeed, although the oaks of America, Canada, Northern and Southern Europe, Japan, etc., are very numerous and approach equality, it may be safely affirmed that the British oak is pre-eminent. In the days when our stout ships travelled the seas, there was nothing else that could have been found strong and sturdy enough to provide the main structure and the planks, and we have an intensely interesting and informative account of the manner in which the utmost care was taken to bring into use the huge branches with their gnarled and twisted growths, so that the limbs of the crown of one single tree were of more value than the huge trunk which supported them.

The Rev. C. A. Johns tells us about a tree which was felled in the New Forest :

"It stood singly in the wood, and extended its massive branches nearly 40 feet each way. Its head was all knees and crooks, aptly suited to naval purposes ; its bole or shaft was short, not exceeding 20 feet in length ; but it was full 6 feet in diameter at the top, and perfectly sound. It was felled in an unusual manner for the preservation of its crooks, which were cut off one by one whilst the tree was standing, and lowered by tackles, to prevent their breaking. The two largest arms were sawed off at such distances from the bole as to make first rate knees ; scaffolds were then erected, and 2 pit saws being braced together, the body was first cut across, half through at the

bottom, and then sawed down the middle, perpendicularly between the two stumps of arms that had been left, at the end of one of which stood a perpendicular bough, bigger than most timber trees. To prevent this being injured a bed was made of some hundreds of faggots to catch it when it fell. This half was so weighty that it crushed a new timber carriage all to pieces the instant it was lodged upon it; and none in the country being found strong enough, the King's carriage was sent purposely from Portsmouth to convey it to the Dockyard. This tree was sold in the 1st place for £40, was bought of that purchaser by a timber merchant for £100, who is supposed to have cleared £100 more; which he might very well do, for the contents amounted to 32 loads of hewed timber, which at 2/6 a foot—no unusual price for naval crooks—amounts to £200 precisely, besides faggots etc. sufficient to defray expenses. The breadth of the tree across near the ground, where it was cut was 12 feet."

It is impossible to catalogue the great number of uses for which oak is preferable to any other British home-grown woods, nor is it necessary, as its qualities are so widely known. Perhaps, however, its uses for panelling or general interior decorative woodwork are not sufficiently recognized. When it was first used in this capacity the superiority of English-grown oak over that of foreign origin was apparent. By degrees its merits appear to have been forgotten, so that importations of foreign competitors became fashionable. Proprietors, proud of their rich inheritance of real old English oak panelling, recognized its value, but new aspirants failed to understand that imported oak was not comparable with British. There is no oak obtainable from any part of the world which will assume the rich golden colour or the attractive figure of English-grown oak, which should not be polished, but left from the tool. Quoting from "A Manual of the Timbers of the World", p. 364:

"When certain individual British oak trees (*Quercus Robur*) are felled, their ordinary heart-wood is found to be partially or wholly changed into a richer toned reddish-brown wood which is known as 'brown-oak'. It was formerly, and indeed it is occasionally even now, among English timber merchants and others in this country, called 'red oak'. The colour is much like that of polished crocodile leather, very variable in character, depth, and richness. It may be uniformly of a comparatively light brown, or again a deep rich brown, having in some cases lighter streaks; while in some portions from one to two inches wide, the ordinary colour does not appear to have been affected at all; again, the warm brown may be spotted and streaked with almost black veins, presenting a rich appearance. This last form is called 'tortoise-shell' pattern."

The beauty and usefulness of this brown oak has never been properly appreciated in England, but curiously enough the demand from America has been persistent and considerable. To meet this demand during the last half-century many thousands of the oldest and best trees which we possessed have been shipped across the Atlantic.

It is commonly known that the sapwood of oak should never be included with any woodwork requiring a long life. The sapwood decays very rapidly, and moreover it is particularly liable to attack by the Lyctus and Zestobium beetles, and fungi. The attack from beetle will often begin within a year after the work has been finished, and will certainly appear in the course of years. Having started, it will invariably spread to the heartwood, and it is therefore essential that sapwood should be entirely excluded. Hitherto it has been rare to find any oak woodwork which has been installed, completely free from the inclusion of sapwood, and the failure to insist upon this practice has been the cause of most, if not all, of the trouble which has been experienced.

With reference to durability, Elwes tells us:

"Many cases have been recorded and published of the great durability of the timber of the oak under ground and under water; but I have come across no relic of the past so interesting in this respect as the prehistoric boat which was dug up at Brigg, in Lincs. in 1884. This wonderfully preserved dug-out was hollowed out of one huge oak log $48\frac{1}{2}$ feet long and approx: 6 feet in diameter, which showed no signs of branches, a log which must have contained nearly 1000 ft. of timber, and which could not be matched now in England, or so far as we know, in Europe or N. America. The boat is 4 ft. 3 ins. wide by 2 ft. 8 ins. deep at the bows, and 4 ft. 6 ins. by 3 ft. 4 ins. at the stern, which was the root end of the tree. The sides are about 2 inches thick, the bottom 4 inches at the bows, and as much as 16 inches at the stern. One stern piece was ingeniously fitted in, though not found in situ, and a large rift on one side had been still more cleverly repaired with wooden patches caulked with moss. No metal had been used in any part of it. The boat was found imbedded in the blue & brown clay which underlies the peat, and is considered on geological evidence, which is given with great detail, to be from 2600 to 3000 years old."

The Lucombe oak (*Q. Lucombeana* (Sweet)) produced something of a sensation in arboricultural circles when in 1773 William Boutcher wrote as follows:

"About 7 years since, Mr. Lucombe of St. Thomas near Exeter, sowed a parcel of acorns, saved from a tree of his own growth, of the iron or wainscot species. When they came up he observed one amongst them that kept its leaves throughout the winter. Struck with the phenomenon, he cherished and paid particular attention to it; he propogated it, by grafting some thousands from it, which I had the pleasure of seeing, 8 days ago, in high flourishing beauty and verdure, notwithstanding the severity of the winter. Its growth is straight, and handsome as fir; its leaves evergreen: and the wood is thought by the best judges, in hardness and strength to exceed all other oaks. It makes but one shoot in the year, viz. in May, and continues growing without intermission: whereas other Oaks shoot twice, viz. in May and in August. But the peculiar and inestimable part of its character is, the amazing quickness of its growth, which I imagine may be attributed (in some degree at least) to its making but one shoot in the year: for, I believe, all trees that shoot twice are some time at rest before they make the second."

Although Boutcher reported the oak as evergreen, it is more correctly described by Elwes as "sub-evergreen", retaining its leaves until the following year.

It appears that Mr. Lucombe had in his nursery a specimen tree of the cork oak (*Q. suber*) near a specimen tree the Turkey oak, *Q. Cerris*, and that he concluded that the flowers were pollinated by the cork tree. This opinion was afterwards confirmed by Sir Hugh Beevor, who raised a similar tree under the same conditions. Messrs. Salter, Simpson & Sons, of Attleborough, have informed me under date of Feb. 1, 1944, that the tree Sir Hugh Beevor showed me forty-five years ago still flourishes, and that its present height is 45 feet, with a circumference of 3 feet 6 inches at 5 feet from the ground. The supposition that the tree is a hybrid of *Q. cerris* and *Q. suber*, which has produced such a remarkably fine timber, proves that we have been both idle and unenterprising, for in truth the wood of the Lucombe oak, if available, might have taken the place of foreign imports, and so released our shipping and increased our revenue. Little data exist upon which to base definite assertions; but the information we have goes to prove that this wood surpasses in

strength and durability more costly varieties that have been imported from abroad.

Elwes tells us that it is doubtful when *Q. Cerris*, or the Turkey oak, was introduced into Great Britain, but since neither Evelyn nor other authorities up to his time mention it, we may safely assume that its introduction dated from about two hundred years ago, when it became very popular throughout the south of England.

English landscape and parklands have a world-wide reputation, and one of the most noticeable and characteristic features is the Turkey oak, which has a grace and beauty all its own. As Elwes emphasizes, it grows not only faster but also straighter than other oaks, and although somewhat similar in appearance there is a subtle difference. The rugged dark-coloured bark first attracts attention, which is afterwards turned towards the noble crown, more widely spreading than the common oak and adorned with a richer green and jagged leaf. The tree produces a very pretty mossy-cupped acorn. The colour of the timber is similar to that of the common oak. It has a bad reputation among craftsmen, as it is harder and heavier to work and more inclined to split in seasoning. It contains a larger proportion of sapwood than the common oak, the outer line of which quickly perishes. The inner line, when carefully dried off, becomes as hard and durable as the heartwood. I am inclined to think that it has been used in the place of ordinary oak, and despite the difficulties already mentioned, I believe that with proper treatment it would be found as useful and durable as other kinds.

In Norway, Sweden and Finland, where the forest wealth plays a most important part in the economic life of the countries, I understand a day is set apart when men, women and children set forth to plant trees. For nearly two hundred years the people of England have enjoyed or been spoilt by a prosperity unequalled, if not unsurpassed, by any other country except America, which ominously reminds us of the state existing in the Roman Empire 1800 years ago. The contrast between the action of our forefathers, to whom we owe the inheritance of our woodlands, and later generations, is nowhere more clearly seen than in the direction of reafforestation.

I have been told that in the eighteenth century Admiral Collingwood used to walk out with his pockets full of acorns, which he distributed over his estate, and the owner of that country, which includes what is now called Chanctonbury Ring, used to ride or walk to the top of the hill every day during the season and sow beech mast or plant a tree.

No words of mine can better express the policy which should be adopted by the State to-day than those written by Evelyn 260 years ago :

"And if thus His Majesty's forests and chases were stored, viz. with this spreading tree at handsome intervals . . . benignly visited with the gleams of the sun . . . nothing could be more ravishing. . . . We should find such goodly plantations for the boast of our rangers, and forests infinitely preferable to anything we have yet beheld, rude and neglected as they are today, when his Majesty shall proceed, . . . to animate the laudable pride into fashion, forests & woods . . . will present us with another face, than now they do. And here I cannot but applaud the worthy industry of old Sir Harbotle Irmistone, who I am told from a very small nursery of acorns which he sowed in the neglected corners of his grounds did draw forth such numbers of Oaks of competent growth . . . and did wonderfully improve both the beauty and the value of his desmesnes."

TESTING WOOD PRESERVATIVES

An article by J. Leutritz (*Bell Lab. Rec.*, 22, No. 4 ; December 1943) describes laboratory and outdoor tests made on wood preservatives used for impregnating poles for communication lines. Sticks ¾ in. square and about 3 ft. long are cut from boards of southern pine sapwood, the uniform size of these samples facilitating calculation of the wood density and the amount of preservative retained, as both are based on volume.

Laboratory tests on preservatives are now carried out in an experimental cylinder by either full- or empty-cell methods. For the former, the air is evacuated from the cylinder containing the specimens, and after a specified time the cylinder is filled with preservative, air pressure being applied to force the latter into the wood cells ; about 30 lb. of preservative can be injected per cu. ft. of wood In the empty-cell treatment the cylinder air pressure is raised to from 25 to 50 lb./sq. in. Then the preservative is pumped in, and the pressure is raised still higher to force the preservative into the wood. Upon releasing the pressure, the expansion of the initial air trapped by the preservative forces out the excess from the wood, and theoretically only the cell wall is coated. Vacuum is applied after the pressure is released to empty the cells more completely. The initial air pressure largely determines the amount of preservative which will be forced out of the cells, while the difference between the initial and final pressures controls the distribution and penetration.

About twenty sticks are selected for each charge and the sample is weighed before and after treatment, the gain being taken as the basis for calculating the amount of preservative retained. Then the sticks are cut at the centre to give specimens treated under identical conditions for comparison by the laboratory rot test and by field exposures. For field-exposure tests the specimens are buried to a depth of 7 in. in a uniform distribution throughout the test plot. They are examined once a year and the amount of decay at and below the ground-line is rated. Since some specimens survive several years or do not fail under exposure tests, a time rating was devised which takes into consideration their past performance.

When a preservative shows promising results in laboratory and field tests, larger material of fence-post size and eventually 10 ft. posts are treated and exposed in 'test gardens'.

ELECTROSTATIC ELECTRON LENSES

An article by K. Spangenberg and L. M. Field (*Elec. Comm.*, 21, No. 3 ; 1943) describes and discusses the measured characteristics of a number of electrostatic lenses, giving the characteristic curves of nine different lenses belonging to three basic types. The forms tested were cylinder lenses of various spacings and diameter-ratios, aperture lenses (parallel plates with circular apertures on the beam axis) of various spacings, and, for comparisons, a lens formed by a cylinder and an aperture in a plate. By interpolating between the sets of curves given, approximate predictions of the properties of lenses of slightly different spacings or diameter-ratio may be made. The test method employed makes use of a

conventional electron-gun with parallel wire grids which, for measurement purposes, are placed before and after the lens to be tested. All the lens characteristics are deducible from measurements made on shadows cast by these measuring grids upon a fluorescent screen placed in the electron beam at a suitable distance from the gun.

The measured characteristics of the electron lenses are presented in the form of object-image distance curves termed p–q curves. These show the relation between object distance and image distance for any ratio of the voltages applied to the electrodes; they also show the lateral magnification associated with any combination of object and image distances. These curves are a graphical presentation of the complete solution of the lens formulæ and they give immediately and directly the relation between all quantities necessary for lens design. The p–q curves further show the interrelation between all the operating characteristics, the quantities involved being object distance, image distance, lateral magnification, and voltage ratio. The object distance (p) is the distance from some reference plane in the lens structure to the point from which the rays emanate. The image distance (q) is the distance from the same reference plane in the lens structure to the point on which the rays are focused. The lateral magnification is the ratio between the height of any corresponding portions of image and object. The voltage ratio is the ratio of potentials on the two components of the electrode structure calculated on the basis of zero potential at the point at which the electron velocity is approximately zero, usually at the cathode. It is only the ratio of potentials and not the absolute magnitude that is of importance, since electron paths are independent of the scale of the potential for the same starting conditions. For completeness, the lens characteristics are also presented in the form of the conventional focal distance curves which show the variation with voltage ratio of the two focal lengths and of the two focal points. All the image-forming properties of the lens may be deduced from these parameters.

FORTHCOMING EVENTS

Wednesday, April 12

Town and Country Planning Association (at St. Martin's School of Art, Charing Cross Road, London, W.C.2, in conjunction with the Exhibition "Reconditioning England"), at 3 p.m.—Mr. F. J. Osborn: "Preservation and Progress".

Institution of Electrical Engineers (Transmission Section) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. G. W. Preston and Dr. H. G. Taylor: "Copper Conductors for Overhead Lines".

Institute of Welding (at the Institution of Civil Engineers, Great George Street, Westminster, London, S.W.1), at 6 p.m.—Dr. L. Reeve: "Factors Controlling the Weldability of Steel".

Thursday, April 13

Genetical Society (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 11.30 a.m.—Symposium on "The Application of Genetics to Plant and Animal Breeding".

Institution of Electrical Engineers (Installations Section) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. C. A. Cameron Brown: "The Electrical Aspect of Farm Mechanization".

Friday, April 14

Institution of Chemical Engineers (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 11 a.m.—Twenty-second Annual Corporate Meeting; at 12 noon—Mr. F. A. Greene: "Our Title—a Reminder" (Presidential Address); at 3 p.m.—Mr. J. G. Bennett: "Coal and the Chemical Industry" (First J. Arthur Reavell Lecture).

Society of Chemical Industry (Plastics Group) (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 2.30 p.m.—Symposium on "Electrical Properties of Plastics" (Mr. H. A. Nancarrow: "A Survey of Thermal Plastics as Dielectrics"; Dr. L. Hartshorn: "The Principles of High Frequency Heating"; Mr. E. Rushton: "Tracking").

Royal Anthropological Institute (joint meeting with the International African Institute) (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Mrs. G. M. Culwick: "Nutrition in East Africa".

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. E. A. Milne, F.R.S.: "On the Nature of Universal Gravitation".

North-East Coast Institution of Engineers and Shipbuilders (at the Literary and Philosophical Society, Newcastle-upon-Tyne), at 6 p.m.—General Discussion on "Radiological Testing" (Speakers: Sir Lawrence Bragg, F.R.S., Dr. S. F. Dorey, Dr. V. E. Pullin, Dr. H. Harris).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Master for Mathematics and Science—The Clerk to the Governors, North-East Essex Technical College and School of Art, Colchester (April 11).

Waynflete Professorship of Metaphysical Philosophy—The Registrar, University Registry, Oxford (April 13).

Lecturer for Degree and National Certificate subjects in Mechanical Engineering—The Organizer of Further Education in Rugby, College of Technology and Arts, Eastlands, Rugby (April 14).

Laboratory Steward in the Science Department of the Doncaster Grammar School—The Chief Education Officer, Education Offices, Doncaster (April 15).

Research Worker (who should be a Physicist with some research experience) in the Coal Treatment Laboratory of the Mining Department—The Secretary, The University, Edmund Street, Birmingham 3 (April 15).

Lecturer (preferably a woman) in Biology—The Warden, Goldsmiths' College, at University College, Nottingham (April 15).

Assistant Hydrographic Surveyors by the Kenya Government Public Works Department—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E 904A) (April 15).

Principal of the Yeovil Art and Technical Institute—The Chief Education Officer, County Hall, Taunton (April 15).

Headmaster of the Junior Technical School—The Chief Education Officer, Education Offices, Doncaster (April 15).

Graduate Assistants (full-time) for Mechanical Engineering, Electrical Engineering, and a Graduate (or equivalent qualification) in Building or Structural Engineering, at the Darlington Technical College and Technical School—The Chief Education Officer, Education Office, Darlington (April 15).

Teacher (full-time) of Engineering Subjects, including Electricity—The Principal, Technical and Art Institute, Queen's Road, Watford, Herts. (April 17).

Assistant (full-time) to teach Workshop Practice, Engineering Drawing, Mathematics and Engineering Science, at the Jarrow Technical School and Evening Institute—The Director of Education, Shire Hall, Durham (April 19).

Senior and Junior Engineers (Mechanical and Electrical) to carry out work of national importance in a Government Department (location, London)—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2097A) (April 22).

Research Metallurgist, preferably with knowledge of Engineering, by well-known North Country firm specializing in the Use and Heat Treatment of High-Carbon and Alloy Steels—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.2019XA) (April 29).

Professorship of Engineering Science—The Registrar, University Registry, Oxford (April 30).

Lecturer (full-time) in Chemistry at the Cardiff Technical College—The Director of Education, Education Offices, Cardiff (May 1).

Chair of Philosophy at the University of the Witwatersrand, Johannesburg—Dr. William Cullen, 4 Broad Street Place, London, E.C.2 (May 1).

Director of the Institute of Medical and Veterinary Science, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

Chair of Natural Philosophy, United College, St. Andrews—The Secretary, The University, St. Andrews (June 15).

Lecturer for Biology and Hygiene—The Principal, St. Katharine's College, Tottenham, at Cary Park, Babbacombe, Torquay.

Lecturer in the Junior Technical School (subjects: Mathematics, Science, Drawing)—The Registrar, Technical College, Cheltenham.

Senior Science and Mathematics Master—The Headmaster, Alleyne's Grammar School, Stevenage, Herts.

Designing Engineer for the Steel Tube Trade in Birmingham—The Ministry of Labour and National Service, Appointments Office, 2 Calthorpe Road, Birmingham 15 (quoting Reference No. 1368).

Assistant Mechanical Engineer for the Sudan—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 1302).

SOCIAL MEDICINE

THE conception of social medicine, which has been the subject of several recent addresses by leading medical men, was, as Prof. Major Greenwood has pointed out in a Chadwick Lecture (*Lancet*, March 13, 1943, pp. 325–328), inherent in the teaching of Hippocrates. In those early days the training of the medical student was a much more personal matter than it is to-day. The student studied with his master, much as he did in the days of our grandfathers; he learned, as medical students of a century ago still did, much about the mode of life of his patients; and medical opinion is nowadays rediscovering the value of this method of approach. It is coming into line with the similar recent movement among biologists, who have learnt that the organisms which they study cannot be fully understood unless they are studied as beings which are inseparable from the surroundings in which they live. It is being recognized by medical men that the individual human patient must indeed be studied as an individual; sympathetic insight into his peculiarities is as important as, and sometimes more important than, knowledge of the malady from which he is suffering; but the group to which he belongs must also be studied, and also all the conditions which civilization imposes upon both the individual and the group. It is the task of social medicine to study such problems as these. Their variety and importance have recently been emphasized by Prof. J. A. Ryle (*Brit. Med. J.*, Nov. 20, 1943, p. 633), who is professor of social medicine at Oxford and head of the first Institute of Social Medicine to be established in Great Britain. A similar department has recently been created by the University of Birmingham, and it would appear that the University of Edinburgh is moving in the same direction with the appointment of Prof. F. A. E. Crew to the chair of public health (see NATURE, March 25, 1944, p. 371).

Social medicine is not, in the opinion of Prof. Ryle, just another name for preventive medicine, and it is not socialized State medicine. It embodies the idea of medicine applied to the service of man and of the community, and seeks to lower the incidence of preventable diseases and to raise the general level of fitness. It lays emphasis on those causes of disease which are rooted in the environment, and so is directly related to social work of all kinds.

How much has already been done in this direction has been indicated by Sir Wilson Jameson, chief medical officer to the Ministry of Health, in his Harveian Oration to the Royal College of Physicians (*Lancet*, Oct. 24, 1942, p. 475). He showed there how profoundly the development of medicine has been influenced by the great social changes which have occurred since the Industrial Revolution, and also how great has been the stimulus given to this development by war. The beneficent work begun by Florence Nightingale has led us far beyond the betterment of the lot of the fighting men. The pages of the medical journals show how much has been

done for the people in general by such means as mass radiography, industrial health schemes and, during the present War especially, by the national food policy, which is based upon recent discoveries in the science of nutrition.

That much more can be done no reasonable man will doubt. Prof. Sargant Florence (Nature, March 25, 1944, p. 363) has put forward some valuable suggestions for the study of variations in human health and efficiency with living and working conditions. Prof. Ryle tells us something of what is already being done at Oxford. He urges us to get away from the specialism and reliance on technical procedures which have been so marked a feature of medicine during the last quarter of a century. As the *British Medical Journal* (Nov. 20, 1943, p. 648) points out, we have taught medical students to think too much about how men die and too little about how they live. We should consider the patient more as an individual inseparable from such environmental factors as the anxieties of a job and a home, economic insecurity, the fear of poverty, and from ignorance of how to live a healthy life and how to use leisure. The importance of such root causes of disease as these has been emphasized by Dr. Geoffrey Bourne in a Penguin Special, "Health of the Future" (1942). Dr. Pemberton (*Brit. Med. J.*, Dec. 11, 1943, p. 754) and Dr. Lloyd-Davies (*Lancet*, Feb. 12, 1944, p. 223) discuss the same theme. Since the War began, Scotland has, with the aid of the Emergency Medical Service hospitals, tried experiments in social medicine. These are described in "Health and Industrial Efficiency: Scottish Experiments in Social Medicine" (London: H.M. Stationery Office, 1943. 1*s*.). These social causes of disease are, as Prof. Ryle points out, being studied in the United States, India, the British Dominions and in the U.S.S.R., and we can learn much from these countries. There is certainly no lack of material for such beneficent work.

Tuberculosis, venereal disease, cancer, rheumatism, influenza, typhoid and other fevers and the blindness which afflicts, as Prof. A. Sorsby points out, some fifteen million people in the world (*Brit. Med. Bull.*, 1, No. 9; 1943; see Nature, March 25, 1944, p. 383) all come within the scope of social medicine. Nor must we think that, when the causes of disease lie in the environment, it is always the ugly and distressing features of that environment that are responsible. Disease may arise, as endemic goitre does, from some feature of the most delightful rural surroundings. The Goitre Sub-committee of the Medical Research Council, in its memorandum on this particular disease (*Lancet*, Jan. 22, 1944, p. 107), recommends, as a national policy, the addition of one part of potassium iodide to one hundred thousand parts of common salt, as a prophylactic, comparable to our national measures against deficiencies of proteins, vitamins and other essential elements in our diet. There are, further, the diseases which do not always kill, but cause incalculable disability, unhappiness and economic loss. An example of these is gastric ulcer, which is increasing greatly; it affects all social groups; it attacks certain temperamental and physical types more than others; it is, in Prof. Ryle's words, a disease of our era of money-getting and money-lack, of occupational and domestic anxiety, of restless living, snack meals and excessive tobacco consumption. It could become as rare as it used to be, if its root causes, which are largely economic, were so fully understood that they could be removed.

It is clear, therefore, that social medicine has a great part to play in social reconstruction after the War. It is clear, also, that the medical student, as well as the qualified medical man, will have to take an active part in this work.

The report of the Royal College of Physicians on social and preventive medicine (see *Brit. Med. J.*, Oct. 30, 1943, p. 553) lays down the lines of a possible future development of social medicine. This report avoids the addition of social medicine as merely another special study tacked on to the existing curriculum. It suggests a modernized course in social and preventive medicine, which should be founded, as the clinical subjects are, on the basic sciences, and should grow and expand through the three clinical years. It should, moreover, be a practical course, operated by a Department of Social and Preventive Medicine in every medical school and should replace the present courses in public health; it should also bring the student into close touch with the active social organizations in the community concerned, especially with the health services provided by the local authorities and with the hospital almoner's department. All medical schools should recognize the importance of problems of industrial medicine; student health services should be available in every medical school and should be used as the instruments of teaching. All hospitals should employ properly trained almoners and psychiatric social workers for the teaching of students as well as for the care of patients; and the Royal College of Physicians should take an active interest in the organization of the teaching of social and preventive medicine, not only to medical students but also to nurses and medical social workers.

The adoption of these admirable recommendations would mean that medical students would learn in a practical way the social and industrial factors which contribute to disease; they would learn methods of social investigation; they would learn all about existing social organizations; they would be able to undertake that admirable mission which Prof. Ryle prescribes for them, the mission of helping, with the aid of their scientific associates and of social workers, to expose social evils and to devise means of removing them. In this way the medical practitioner of the future would fulfil, in a wide and modern sense, the traditions of a profession which was, to the fathers whom we remember, the noble calling of friend and counsellor as well as mender of physical and mental ills. Such a calling will require and will attract the best type of woman and of man. Its teaching and research facilities should be endowed and assisted to the fullest limit of our capacities, so that they may be intensified and expanded to meet the manifold requirements of the post-war world.

INTRODUCTION TO GEOLOGY

Geology for Everyman

By the late Sir Albert Charles Seward. Pp. xi+312+8 plates. (Cambridge : At the University Press, 1943.) 10*s*. 6*d*. net.

BOTANIST, geologist and lover of Nature and of his fellow-men, Sir Albert Seward finished writing this book three days before his sudden death. It was evidently a labour of love—this endeavour to transmit to others his enthusiasm for the only real open-air science. Not only is the book an appeal to folk to take up geology as a hobby, but also it sets out "to present a case for the inclusion of an intelligent interest in" the subject "as part of that intellectual equipment we call culture, culture that has been defined as what remains after we have forgotten all we learnt at school". His descriptions "are not intended to serve as an elementary text-book" ; his "hope is that they may be used as stepping stones to something higher and more scientific".

Such a book has long been needed, for geology has receded from the position it held a century ago as part of the natural equipment of an educated person. To-day its principles are little understood, and its discoveries and their implications are ignored. Perhaps people are put off by the scientific jargon which prevails in geology to an undue degree ; but Seward's book proceeds in the first few chapters with many delightful personal touches to arouse an interest in the basic principles of the science with a minimal use of technical terms, though he pleads that "some of the technical terms in common use by geologists should find a place in the vocabulary of all educated people". It is perhaps questionable whether the bare minimum of principles given here will by itself provide a complete novice with sufficient knowledge to take the fullest advantage of the main part of the book which follows. This is devoted to the record that the rocks provide of an ever-changing geography brought about through the slow grinding away of land, and the growth of deltas, plains and mountains through the ceaseless movement of the crust and the equally inexorable changes of climate. Throughout, Seward uses the changing geographical scene as the background to organic evolution.

It is natural that the author of "Plant Life throughout the Ages" and of the standard text on "Fossil Plants" makes evolution one of the main themes of his book, with particular emphasis on the changes in plant life from age to age. As this is an aspect of the stratigraphical record to which Seward had devoted his life, and one that rarely receives adequate recognition in geological text-books, the treatment is rightly developed on a fuller and more satisfying scale than that accorded to the animals, though their palæontological record is not neglected. General readers for whom the book is intended will be attracted to the study of fossils through the clear way in which their significance is brought out.

The method adopted in this book of treating the geological periods from the newest to the oldest has the sanction of authority in that it was used by Lyell ; but it inevitably leads to repetitions, some of which are irritating and tend to distract from the sequence of the events. But in this book each chapter is an exposition of one or two major principles or important incidents rather than a description of an ordered cavalcade of events. Doubtless Seward intended to excite interest in some particular part of the geological record and to show what sort of things can be deduced from it, and for this purpose was not over-concerned with its dating. Here are some of his themes : Britain under the arctic conditions of the Ice Age, post-Glacial climatic changes and their effects on the vegetation, de Geer's system of geochronology, the changing floras of the Tertiary and their interpretation in terms of climate, the building of the Alpine chain, the break in mid-Cretaceous times between ancient and modern types of plants, the salt lakes and deserts of the New Red Sandstone, the origin of coal, the value of careful fossil collecting and the contribution to science that it can make even in the hands of amateurs.

The chapters relating to the Cretaceous, Tertiary and Glacial periods are very interesting and attractively written, and so are the ones on fossils ("Medals of Creation") and on the "Procession of Life" ; but strangely enough the one on the origin of coal is disappointing and surprisingly misleading over the composition of that much-analysed substance. Naturally the older formations are more difficult to deal with ; but a sense of their influence on scenery, their antiquity and of the strangeness of the forms of life that they contain, is vividly conveyed. "The world, to our limited vision, appears to be almost static ; mountains we have thought of as symbols of eternity, seen through geological spectacles, take their place as episodes in a series of events which have moulded the changing features of the earth's face. The rocky covering of the world viewed by geologists, 'foreshortened in the tract of time', reveals itself as a dynamic mobile crust responding from age to age to constructive and destructive forces which have operated since the earth's early youth."

This is a book so full of wisdom, wit and learning that it cannot fail to convey to its readers the author's lifelong enthusiasm. For this reason alone it is particularly welcome to-day, for it will take an honoured place among the instruments designed for that wider education of young people and adults which we all look forward to after the War. It will find its most appropriate niche in the school library and on the bookshelves of students' hostels, clubs and unions ; but it should also make a strong appeal to lovers of the country and to the not inconsiderable number of persons who like 'to go geologizing'.

L. J. Wills.

PLANT GEOGRAPHY OF THE MEDITERRANEAN REGION

Das Pflanzenkleid der Mittelmeerländer

Von Prof. Dr. M. Rikli. Lieferung 3. Pp. 241–352+13 plates. Lieferung 4. Pp. 353–436+14 plates. (Bern : Hans Huber, 1943.) 9 Schw. francs each.

THE publication of another two serial parts of Dr. Rikli's book on the plant cover of the Mediterranean region completes volume 1 of this work (for an account of the first two parts see Nature, 152, 117 ; 1943). Part 4 includes the title-page and list of contents of the volume, together with a short preface by the author. In the latter it is noted that the large number of maps showing the geographic distribution of numerous different species in the region have been prepared on the basis of the classical floristic works and partly in consultation with specialists on certain parts of the Mediterranean basin. The advantage of these maps is the rapidity with

which a general impression of the distribution of a species may be obtained; but on the other hand, they tend to imply a completeness of knowledge which is not actually existent, and gaps within the total area of distribution are as a rule disregarded. Their primary object is to serve as a stimulus for the collection of further data, so that in a later edition the maps may be supplemented or corrected as is found necessary, and communications on this subject are invited by the author.

The seventh chapter, dealing with the natural land of the cultivable belt, is now completed, and the eighth chapter, which studies the distribution by altitude of the various formations discussed, brings the first volume to a close. A note at the end of the seventh chapter states that the cultivated land is to be treated in Chapter 10. The normal disadvantage of any such serial publication, namely, that some illustrations to which allusion is made or pertinent references to the literature have not yet appeared, although it certainly exists in the present case, is not so serious as to be of any significant hindrance to the use of the work.

The natural formations described in the remainder of the seventh chapter comprise large-shrub formations, the xerophilous small-shrub formations, tracts of herbaceous growth and of tall herbaceous, large-leaved plants, and sea-shore, dune, lakeside, marsh and cliff formations of various kinds. Under the first-named the section on the pseudo-maquis is terminated, and the sibljak formation is described. The sibljak is a sub-Mediterranean association of summer deciduous therophytic shrubs or shrub-like trees which are able to bear—in addition to a dry, hot summer—a fairly severe winter with occasional low temperatures, cold winds, and often also a long covering of snow. It is never found near the coast, but principally in the more continental part of the eastern Mediterranean, although it is recorded also for the west, for example, the centre of the Iberian peninsula. Some fifteen to twenty species participate in the structure of this formation, which is generally seen above the evergreen level and is considered in many localities, such as steep rocky slopes, scree on slopes, etc., to be an original association, the area of which has become greatly enlarged, however, through the destruction of forest.

The xerophilous small-shrub formations described are the steppe of succulents and thorn bush limited to southern Morocco, the ericaceous heaths—in the Mediterranean a type of vegetation principally of the submontane level, and in the Iberian peninsula of unusual richness—and the garigues. The name 'garigue' is of Provençal origin, and is applied to a more or less open association of small shrubs, seldom higher than 1–1·5 metres and often rich in ethereal oils. Between maquis and garigue all manner of transitional formations exist. Sixteen different types of garigue are distinguished and described. Their use for grazing is generally very intensive, as a result of which many plant species become eliminated in the course of time, while others, such as certain thorn bushes and especially poisonous plants (*Peganum Harmala*), become dominant. Where the humus-deficient soil of the garigues becomes still shallower and dries up more rapidly, even the small shrub growth is endangered, and its place is gradually taken by an ephemeral growth of therophytes and by geophytes. This formation is described as 'herbaceous grazings (rock grazings)', the word 'Trift', which means a pasture or grazing, being used in preference to 'Heide' or 'heath' in order to avoid confusion with the ericaceous formation. The word indicates, too, the only use—periodic grazing—to which these lands are put. Typical of the formation is its great abundance of species and their magnificent colouring when in flower. A different type of vegetation is seen in the association of tall, large-leaved herbaceous plants, 1–2 metres and more in height, found in moister, better soils of (*a*) forest regions and (*b*) in open association in dry regions.

In the consideration of the strand and marsh formations there are treated successively the submerged associations; the sparse vegetation of the strand itself; the vigorous plant-growth found amid heaps of large rocks, which is quite different from that of similar rock groups in the mountains; the vegetation of the littoral shifting-sand zone and of the littoral dunes respectively; that of the salt marshes, the freshwater marshes, of ponds (depressions only periodically flooded and dry for practically the greater part of the year), lake- and river-sides; and finally, the cliff and strand rock flora affected by surf and spray. Dunes are found on all the flat coasts of the region, but especially along the Atlantic coasts of the Iberian peninsula and Morocco (Agadir and Mogador) and on the shores of the Sirte region in northern Libya. Successful efforts at the stabilization of dunes between Tripoli and Lebidah (also named Leptis Magna or Neapolis) are described. In regard to the river- and lake-side flora, it is noted that boreal species form the main contingent of the plants present; specifically Mediterranean elements are rare, and it is almost the papyrus alone that is of definitely southern origin.

The classification of the Mediterranean plant cover in accordance with altitude is impeded by the fact that the various levels are not so sharply defined as in central Europe, and the actual elevation at which associations or their components are found varies very considerably with the region. This is discussed with particular reference to the evergreen, Mediterranean culture belt as found in the Iberian peninsula, Corsica, the Apennine peninsula, the northern part of the Balkan peninsula, Greece, the Near East, and the Atlas lands respectively, and it is concluded that, generally speaking, the limit of the altitude line or belt becomes higher from north to south and lower from west to east. Allowance being made for variation of this nature, three more or less clearly defined altitude lines or vegetation belts ('Hohenstufen') are distinguished, namely, (1) the evergreen, Mediterranean culture belt (also described as the olive girdle or, from its most important formation, the maquis girdle); (2) the Mediterranean mountain belt, embracing the region from the upper limit of the evergreen belt to the upper forest- and tree-line; and (3) the orophytia belt. Of the first, the natural land formations have already been described in the seventh chapter, and reference is made to Chapter 10 (not yet published) for those of the cultivated land. A description of the second belt occupies the major part of the eighth chapter, and discussion of the third is reserved for a further section.

Originally the Mediterranean mountain belt consisted for the most part of forest, but the spoliation of centuries has led to far-advanced deforestation in many parts, where the place of the woods has been taken by impoverished, grazed garigues. In other parts, however, the woods remain and present a constantly changing landscape made up of different kinds of trees. The influence of the forester is as yet

insignificant. The woods are composed either of deciduous trees, especially *Castanea sativa* and *Fagus silvatica*, occasionally also *Quercus Ilex*, or of a large number of conifers of the genera Picea, Pinus, Abies, Juniperus, Cedrus and Cypressus. The distribution and nature of these woods and their components are described in considerable detail.

Finally, there are described the formations which have possessed themselves of the areas denuded of forest. Of these the most important is the garigue, the capacity of which for establishing itself on such lands exceeds that of any other formation. Not only does it occupy wide tracts of the former woodland girdle, but also it often reaches far above the upper limit of the Mediterranean forest- and tree-line.

G. M. ROSEVEARE.

A SURVEY OF PLANT DISEASE

Report on Fungus, Bacterial and other Diseases of Crops in England and Wales for the Years 1933–1942

(Ministry of Agriculture and Fisheries, Bulletin No. 126.) Pp. iv+100+8 plates. (London: H.M. Stationery Office, 1943.) 2*s*. net.

IT is sometimes a little difficult to attain true perspective in a science like plant pathology, where facts are accumulated in a manner necessarily fragmentary and sporadic. Diseases never occur in standard measure, either of space or time, and Pasteur's dictum that chance favours only the mind that is prepared applies with special emphasis to the study of plant pathology. It is very appropriate that a periodical review be made of the occurrence of all diseases, and Mr. Moore, who is mycologist to the Ministry of Agriculture and Fisheries, has gathered together such information for England and Wales. He has had numerous collaborators, and the review follows an earlier bulletin (No. 79) which covered the five years, 1928–32.

One of the outstanding indications of the bulletin is the increasing number of plant maladies which are now recognized. This is, in all probability, due to the fact that cultivators are now more aware of diseases than formerly. We are separated by little more than half a century from the time when blights upon crops were regarded as 'acts of God', as little amenable to control as the whirlwind. The increasing tempo of plant cultivation since the outbreak of war has brought the plant pathologist much extra work, but has also given him a further harvest of scientific facts. Moreover, such glances as are vouchsafed into what might be called the archæology of plant pathology show that diseases were often present on fragments of plant material preserved from bygone times. Greater awareness of disease is also shown by the increasing number of deficiency troubles which are included in the bulletin under review. The work of the pathologist here merges with the activities of the physiologist, with ultimate advantage to both.

The bulletin arranges the diseases of each host according to the nature of their causal agents, and in the order fungi, bacteria, viruses and non-parasitic. Pathology of ornamental plants, of hop, mushroom and flax, and of fruit and vegetables is recorded, in addition to the maladies of all farm crops. An indication of the thoroughness of compilation is given by the mention of Pythium root rot and a mosaic virus on watercress, the notice of *Ovularia Nymphærum* on water-lily, and a description of soft shell of the walnut; and diseases of the more usual crops receive no less encyclopædic treatment. Symptoms of the more recently discovered troubles are given in sufficient detail for field diagnosis, and some are illustrated in the eighteen excellent half-tone figures. Common names are in accordance with those recommended in the "List of Common Plant Diseases" of the British Mycological Society. The review certainly achieves the purpose of keeping the plant pathologist up to date.

Some effort has been made to correlate the incidence of disease with climate. Synopses of the weather in each of the ten years are given, and in some cases broad conclusions are possible. The general effect of weather on potato blight has been recognized for some time. Hot, dry summers in 1921, 1929, 1933–35 and 1940 rendered blight of little economic significance as a foliage disease. Wet and sunless periods between June and September in 1926, 1931, 1936 and 1942 brought very severe attacks of blight. A wet May seems to portend a bad year for apple scab, and abnormal rainfall in July and August renders the downy mildew of hops very destructive. Chocolate spot of broad beans can assume epidemic proportions in periods of dull, showery weather between April and July. Mr. Moore very rightly points out the need for more extensive and intimate studies of the 'micro-climate' within an infected crop. Closely connected with climatic survey is the question of estimation of disease intensity, and here the excellent pioneer work of the British Mycological Society is incorporated in the bulletin.

The incidence of wart disease is interesting. Its spread during the last twenty years has been greatly reduced by the operation of the Wart Disease of Potatoes Orders. Outbreaks since 1933 have averaged about 87 per year, and this figure has not been exceeded by the average for the war years. Onion smut, another disease subject to legislation, appears to be increasing, though it is probable that most of the new cases represent long-standing infection; they were discovered during an intensive survey by the Ministry's inspectors. The problem is complicated by the length of time the fungus can remain infective in the soil—at least seventeen years. A slight decrease in the amounts of severe mosaic and leaf roll is recorded in potato crops raised from new Scotch or Irish seed during the war years. There is also less virus infection in crops raised from once-grown seed. The bacterial disease mentioned most frequently is crown gall (*Bacterium tumefaciens*). It occurs upon such widely varying hosts as dahlia, raspberry, apple, vegetable marrow, tomato, mangold, chrysanthemum and many others. Of deficiency diseases, that of potassium appears to be most frequent, and most cases are reported in the war years. Magnesium, boron, manganese and calcium may also cause their respective deficiency symptoms. One type of injury likely to be recognized more widely in the future is that due to acid soil. Plants growing at the lower limit of their *p*H range frequently exhibit characteristic symptoms, and their tabulation is one of the future tasks for the joint efforts of plant pathologists and physiologists.

The bulletin is far more than a list of plant diseases. It is an informative conspectus of the intelligence section of phytopathology. Mr. Moore frequently uses a somewhat conversational blend of history and etiology, so that his descriptions are not merely arid records, and his pages often indicate the direction which future investigation should take.

JOHN GRAINGER.

BIOLOGICAL CONTROL AS A SUPPLEMENT TO CHEMICAL CONTROL OF INSECT PESTS

By DR. W. E. RIPPER
Pest Control Ltd., Cambridge

WHILE chemical control is in general the most effective method of pest control known and therefore the most generally used, an increasing amount of experimental proof has accumulated during recent years showing that this method has a very serious limitation. Repeated applications of chemical control result in an unintended artificial selection of those mutants within the pest population which happen to be resistant to the poison used. The progeny of these surviving mutants develop races of the pest which are more difficult to control than the general population.

This disturbing phenomenon was first noticed by Melander in 1914 on San José scale, *Aspidiotus perniciosus* (Comst.)[1]. Fifty years after the importation of this pest into the United States it was found that, after several treatments with lime sulphur had been carried out every year in the State of Washington for twenty-five years, this scale insect had become much more resistant to lime sulphur.

Next, Quayle in 1916[2] showed that a strain of the red scale, *Aonidiella aurantii* (Mask.), at Corona in California, was more resistant to cyanide fumigation than the general population of this pest elsewhere. Since the introduction of tree fumigation in 1886, prussic acid has given unusually effective control over a large part of the red scale infested area of California, but in certain districts, an increased resistance was found a few years previous to Quayle's publication in 1916. For more than thirty years the increase of the distribution of the resistant strain has been observed and the phenomenon extensively investigated by Quayle during 1916[2] and 1938[3] and Woglum in 1925[4], who established that the survival in areas where the non-resistant strain abounds was of the order of 1 per cent, while in the area where the resistant strain had developed it was 20 per cent. As the red scale has under present spraying schedules at least three generations to one treatment, such a difference in survival was of high economic significance, and the difference in susceptibility was noticed by the fumigation contractors operating in that area. Environmental influences were excluded by rearing sixty generations of colonies of the resistant and non-resistant races under identical conditions, when it was found that the same differences in susceptibility towards cyanide persisted.

Dickson in 1940[5] was able to show that the factor of resistance is inherited and situated in the *X*-chromosome and is therefore sex-linked.

From the general aspect of chemical control, it is important that the resistant strain of the red scale was also found to be less susceptible to two other fumigants, methyl bromide and ethylene dioxide.

Increased resistance to prussic acid was established for two further citrus scales, namely, the black scale, *Saissetia oleae* (Bern.)[2], and the citricola scale, *Coccus pseudomagnoliarum* (Kuw.)[3]. The spread of the resistant strain of the latter scale was dramatic in its rapidity; the resistant strain was first noticed in *one* orchard in 1936; but in the next three or four years the area of its distribution extended over most of the region infested by the citricola scale in Southern California. As natural barriers cross this area, the selection of this resistant strain must have occurred simultaneously from independent mutants. Thus in a very short period the effect of chemical control had changed from satisfactory to very unsatisfactory results.

Race segregation resulting from the application of insecticides is not confined to scale-insects but has also been found in the codlin moth, following treatments with arsenate of lead. The discovery of resistant strains as a result of chemical control on so different a type of insect first attracted attention to the general character of this sequel to chemical control. The most resistant strain was found in Colorado, where codlin moth had appeared in 1891, and spraying with arsenate of lead had been started three or four years later. In 1900 two sprays were necessary to obtain a satisfactory control, and by 1930 eight, ten or twelve.

This resistant strain was investigated by Hough[6,7,8], who took a stock of the codlin moth from Colorado to his laboratory in Virginia and studied it there in comparison with the endemic codlin moth population. It was found that the Colorado strain was not only able to enter apples sprayed with arsenate more successfully than the Virginian strain, but also showed the same superiority in its resistance to other spray residues, such as cryolite, barium fluosilicate, rotenone, nicotine, cuprous cyanide. The Colorado strain was also significantly resistant to cyanide fumigation in the incubated-egg stage and in the larva stage.

Hough was further able to demonstrate that a strain with similar characteristics to the Colorado strain can be bred from the Virginian codlin moth populations by artificial selection. He held the opinion that mutants of the same higher resistance existed in all codlin moth populations.

On a very different type of insect, the larva of the primary screw worm, *Cochliomyia americana*, Knipling[9] was able to demonstrate that a greater resistance against phenothiazine could be acquired and inherited.

Increased resistance against tartar emetic sucrose bait has been noticed in the Citrus thrips[10]. An interesting feature of this case is the development of a resistant strain after this spray chemical had been used for three or four years only. Resistance developed in a fairly big area over a space of about a hundred miles with big stretches of uncultivated land and mountain barriers between, so that it would seem that mutants may have arisen at several foci simultaneously.

Thus, in the life-time of one entomologist at least seven species of injurious insects have evolved races which are more resistant to certain insecticides than the ordinary populations or any of the populations of twenty-five years ago.

In some cases the resistance is not specific towards one chemical but results in the pest being more difficult to kill by a whole range of chemicals, so that it seems that the segregation of these new resistant races is a problem of rapidly increasing importance and far-reaching effect on our conceptions of chemical control. If it is remembered that, as the above described facts show, this increasing resistance can be acquired in a period of repeated applications of chemicals varying from three or four to thirty years, it is not difficult to appreciate the concern of the entomological profession over this man-bred segregation which renders the pests more and more inaccessible to our control measures.

The position has been admirably surveyed by Harry

Smith[11] and Quayle[12] in its genetic, entomological and economic aspects, and Smith concluded that the segregation of resistant races "is an obstacle to the practical usefulness of entomology, the surmounting of which will require not only all our ingenuity, but all our capacity to organise and ability to enlist the active co-operation and interests of geneticists, physiologists, ecologists, and taxonomists. It is my firm conviction that recognition of the practical significance of the effect of man's activities on the racial composition of insect populations, followed, of course, by group attack for solution of the problems arising from it, will become a milestone in the progress of both the science and the art of applied entomology".

As the segregation of resistant races is caused by the survival of resistant individuals, it seems expedient to direct our attack against these surviving resistant mutants. As shown by Hough[8] and Yust[13], the latter may possess a higher resistance against a variety of chemicals; it seems, therefore, obvious that the reduction of these survivals must be attempted by a totally different method, for example, by biological control. For this purpose, we require an insecticide which would kill a much greater proportion of the pests than of the predators and parasites of the pest. Such an insecticide is referred to in the following as a *selective insecticide*. In such a case the surviving beneficial insects should clear up the resistant mutants of the pest before the latter can propagate and develop a resistant strain. In other words, we are searching for a type of insecticide capable of effecting a shift of the oscillatory equilibrium between the population of the pest and the population of parasites and predators in such a direction that the latter outnumber the former, either immediately or in a short interval after spraying, and lead to a complete annihilation of the pest population in the treated biotope.

The development of selectively poisonous chemicals would not only enable us to prevent segregation of resistant strains, but would also be desirable for economic reasons. Many treatments with insecticides lead only to relief from the pests for the time being, because immediately after treatment the pest population builds up quickly and necessitates a repetition of the treatment, often, during the growing season, within ten days or a fortnight.

In many cases it has been observed that the re-infestation after chemical treatment builds up more quickly than the original infestation. The theory underlying this phenomenon was described by Volterra[14] in his consideration of the variations and fluctuations of the number of individuals in two animal species living together, one species preying on the other, and was communicated in what he called the "Law of the Disturbance of Averages": "If an attempt is made to destroy the individuals of two species uniformly and in proportion to their numbers, the average of the number of individuals of the species that is eaten increases and that of the individuals feeding upon the other diminishes". Hence the destruction of a whole section of the population of hosts, predators and parasites may result in a subsequent relative increase of the host and relative decrease of the parasite, a phenomenon only too familiar to all entomologists engaged in pest control operations, as a frequent sequel to chemical control. Such deleterious effects of spray treatments on the parasites of the pests has often been recorded (Driggus & Pepper[15]; Driggus & O'Neil[16]; Boyce[17]).

If the chemical control necessitates a repetition of the treatment, it is obvious that the application of the method will only be an economic proposition on higher paying crops. The use of selective insecticides, apart from preventing the segregation of resistant strains, will also reduce the number of spray operations necessary and thus bring pest control methods within reach of growers of cheaper, that is, farm, crops.

All these limitations of chemical control as practised to-day make the introduction of selective methods of pest control highly desirable.

Some attempt has been made to develop such selective insecticides by utilizing the differences in the physiology of the phytophagous insects on one hand and the carnivorous or parasitic insects on the other hand. For this purpose, stomach poisons were prepared, the individual particles of which were coated with substances digestible only by certain groups of phytophagous insects. By this means the poison was rendered indigestible to adult Hymenoptera and certain other insects and therefore harmless to parasites and certain predators[18].

Another attempt towards selective eradication of pests was based on the difference in toxicity of nicotine vapour to aphides and parasites or predators. It can be shown that short exposures of 40 sec.–1 min. to nicotine vapour at a temperature of 60°–80° F. and of a concentration of 0·8 mgm. per litre, proves fatal to 80–99 per cent of certain aphides, but does not seriously affect coccinellids, syrphids or the larvæ of the Braconid aphid parasite Aphidius, which lives and pupates in the aphides.

These beneficial insects surviving the nicotine vapour treatment outnumber the surviving aphides and decimate the latter in the weeks following the treatment, so that after an initial high percentage of kill, the infestation is further reduced. Thus, this method gives the best control of aphides hitherto demonstrated on farm and market garden crops in Great Britain, and has therefore been used on a large commercial scale during the past four years. It is called field fumigation or gassing.

The method fulfils all requirements postulated earlier for a selective insecticide, and a quantitative study of changes in the population of the pest and its natural enemies caused by the selective action of insecticide is therefore of general interest in ascertaining the mechanism of the combined action of chemical and biological control, and more especially to determine whether the limitations of chemical control as generally practised are overcome.

While the destruction by parasites and predators of those aphides surviving the fumigation has also been observed on infestations of black-fly, *Aphis fabae* (Scop.) and the potato aphis, *Myzus persicae* (Sulz.), none is more suitable for a quantitative study of the phenomenon than the cabbage aphis, *Brevcoryne brassica* (L.).

The biotope of the Brussels sprout field lends itself particularly well to population studies, because the number of Brussels sprouts plants per acre is small, and under Bedfordshire cropping conditions constant (4,840). The plants are set at intervals and the infestation by cabbage aphis lasts for many months, May–November. The cabbage aphis has a fair number of predators—coccinellids, *Coccinella 7-punctata* (L.), and *Adalia bi-punctata* (L.): the larvæ of syrphids, *Syrphus ribesii* (L.), *S. balteatus* (De G.), and *Catabomba pyrastri* (L.); and the larvæ of cecidomids, *Phaenobremia* sp. (Petherbridge &

Wright[19]); and one important parasite—*Aphidius brassicæ* (Marsch). In a normal year these beneficial insects live with their host in a state of equilibrium for the greater part of the year, resulting in a severe infestation of the plants by the aphides, which cause a good deal of damage. At the beginning of the autumn, parasitism increases and the pest, having spoilt the crop, is often overwhelmed by its natural enemies at the end of the growing season.

This is in agreement with the results of the work of Ullyett[20], who has shown that, despite the higher biotic potential of the parasite, the latter is at a disadvantage compared with the aphis because (1) of super-parasitism, (2) some of the parasitized aphides are able to reproduce before the parasites kill them, and (3) every individual aphid is reproducing.

In order to prevent damage it has become the practice to gas the Brussels sprouts in the middle of August or in September, vapourizing up to 3½ lb. of 95 per cent nicotine per acre. All the cabbage aphides are exposed to toxic fumes for 60 sec. under a gas-proof drag sheet which provides a movable fumigation chamber fitted to a gassing machine moving at a speed of one mile per hour (see Fig. 1).

To study the population changes of aphides and their enemies, a method of measuring the population before and at regular intervals after treatment was developed. As the population of aphides per plant shows great variety in size, plants were sampled at random and grouped in three classes according to the various degrees of infestation. Representative samples were then taken of several plants in the three classes. These plants were then analysed by counting (1) predators, (2) live aphides showing no signs of advanced parasitism, (3) aphides killed by parasites. Figures thus obtained for 'parasitized' aphides refer only to those in advanced stages of parasitism, when the aphides are dead and show a change in colour. This simplified the counting by avoiding dissections and introduced a constant error which does not obscure the phenomenon. For counting, a gravimetric method was used. It was possible for one full-time worker to ascertain the population of a field in two to three full days' work. Population counts were taken by this method before gassing and immediately after treatment, and at intervals later to show the after-effects of the selective insecticide on the aphis population.

As fumigated aphides drop off the plants, the mortality achieved by the direct effect of gassing was ascertained by fixing black cloths under a number of plants before the treatment and counting the live and dead insects remaining on the plants and those collected on the cloths. 'Parasitized' aphides were then transferred to test tubes and the parasites reared.

The results obtained from this survey by the above method follow a general pattern, which will be described, using as an example data relating to the field of Messrs. Bates Bros., of Roxton, Beds (see Fig. 2).

The infestation on the Brussels sprouts in the field to be treated (B) and equally in the adjacent control (A) was severe, 98,000,000 and 22,000,000 aphides per acre respectively. On both fields the parasitism, as expressed as percentage of dead aphides parasitized by *Aphidius brassicæ*, was low, 3·0 per cent and 3·1 per cent. The number of aphides per one syrphid larva was 101 and 103. There was no infestation by *Entomophtora aphidis* and there were no predators except syrphid larvæ. The weather was dry and hot.

The field B was fumigated by two commercial tractor-mounted gassing machines of Pest Control Ltd., Model 1942, on July 28 between 1 and 5 p.m.: the temperature was 78° F. and the drop-off of the dead aphides instantaneous. The first counts were taken on July 31, showing a kill of aphides of 99·9 per cent.

Gassed 'parasitized' aphides were collected and the parasites reared in comparison with 'parasitized' aphides, from untreated fields. 100 per cent emergence was recorded in both cases.

On the treated fields the aphis population on July 31, three days after gassing, was found to be only one-thousandth part of the population before gassing. After a further three days a fourfold increase in the number of living aphides was counted, but this was again reduced to less than a quarter sixteen days after treatment. The infestation was then still of the order of a thousandth part of the initial population, and three weeks after gassing no living aphid could be found on the field. All aphides which survived the gassing had been killed by parasites or predators irrespective of whether they were mutants more resistant to nicotine, aphides which escaped merely because they were in a particularly protected position, or chance arrivals migrating to the field after the treatment. On August 18, three weeks after the treatment, on the whole field no living and only a few parasitized aphides could be found.

With a non-selective insecticide, we should expect the pest population to build up again immediately after the treatment during the summer months, particularly in cases such as the cabbage aphis, which migrates continually. This migration, incidentally, is probably responsible for the increase of the aphides between the third and sixth days after gassing.

The treated field remained free from aphides until the end of the fourth week after the treatment, and only then the infestation built up until, fifty days after treatment, the population reached again a serious infestation.

It is obvious that practical control would be carried out in such a way as to prevent re-infestation. Therefore, either the treatment would be deferred to such a date as would ensure that the period during which the parasites keep the newly arriving migrants in check extends over the migrating period, or the treatment would be repeated when the protecting effect had reached its end.

FIG 2. EFFECT OF CHEMICAL AND BIOLOGICAL CONTROL ON THE POPULATION DENSITY OF CABBAGE APHIS AND ITS PRINCIPAL ENEMIES, THROUGH TREATMENT WITH A SELECTIVE INSECTICIDE.

If we compare the densities of the aphis populations on the treated and untreated field, we see that the population on the untreated field remained almost stationary through the summer and decreased towards mid-September to about half its magnitude on July 28, the date when the first field was gassed.

If we look at the number of parasitized aphides per acre we observe a great change in the proportion of parasitized aphides to living aphides, before and after treatment. While the number of aphides is reduced to one thousandth of its original figure, the number of parasitized aphides is only reduced by a half. Thus the superiority in the number of parasitized aphides over living aphides became paramount until, after three weeks, the parasites had completely wiped out the living aphides. At that time, as mentioned before, *no* living aphid could be found—merely a few dead parasitized ones.

Adult parasites feed normally on the honey dew excreted by aphides, and as the aphides had disappeared and no substitute food had been provided, the Aphidius adults emerging from the parasitized aphides three weeks after treatment were left to starve, the newly arriving cabbage aphis migrants being unable to support them. Thus most of the parasites died of starvation and a new big infestation was therefore built up.

It is worth noting that the parasites which, after treatment, outnumbered the cabbage aphis, remained in this overwhelming majority until the aphides were wiped out, while the hover fly larvæ which, three days after treatment, were only slightly fewer than before treatment, had almost disappeared so early as six days after treatment. Most Syrphid larvæ pupated, and female hover flies were not sufficiently induced by the small number of aphides left after treatment to lay their eggs, so that the population of hover fly larvæ decreased rapidly. Hover fly larvæ disappeared completely three weeks after treatment, showing that they can be relied upon to help in the cleaning-up of the pests *immediately* after treatment by vapourized nicotine. But as their superiority in number soon disappears, the population of hover fly larvæ, though a powerful factor, is a short-lived one in the biological control of the pest following the application of a selective insecticide.

In the untreated field the populations of parasites and hover fly larvæ remained fairly constant for four weeks after the date of treatment of the gassed field, but towards mid-September the percentage of parasitized aphides had significantly increased in accordance with the usual trend.

That the results described are typical was shown by the close agreement of further data obtained by quantitative analyses of aphis population counts after gassing on other fields. The mortality varied with the temperature at the time of treatment, but even when it was so low as 87 per cent, the after-effects of the treatment followed the same general pattern, provided that there was an initial parasitism and an initial population of predators before the field was treated.

Treatment with a selective insecticide should not be carried out at too early a stage of the infestation before the beneficial insects are established.

Summing up, it has been shown that chemical control is greatly limited by the development of resistant races of pests through artificial selection caused by the insecticide, and it is proposed to overcome this limitation by a combination of chemical and biological control through use of selective insecticides.

To demonstrate the latter effect field fumigation of aphis infestations by nicotine vapours in short exposures was used. At a dosage of 3¼ lb. nicotine (95 per cent pure) per acre, and an exposure of one minute, a mortality of the cabbage aphides at the rate of 85–99·9 per cent was obtained at temperatures above 60° F., while Coccinellids, their larvæ and pupæ, and the larvæ and pupæ of Syrphids and of the Braconid parasite Aphidius, showed no mortality. Cabbage aphides surviving the nicotine treatment, whether more resistant to nicotine or not, were all

killed by predators and parasites immediately, or by parasites within a period of three weeks, after the fumigation.

As no resistant mutants thus survived the treatment by the selective insecticide and the following attack by the beneficial insects, any possibility of a segregation of a more resistant race was precluded. The search for further selective insecticides would therefore seem to be a promising approach to the extension of the usefulness of chemical control. More rapid progress could be achieved if the comparative physiology of the economically important insect groups were systematically explored.

SOLAR PHENOMENA AND GEOMAGNETISM

A DISCUSSION on "Solar Phenomena and Some Allied Geophysical Effects" was held at a meeting of the Royal Astronomical Society on March 10. The president of the Society, Prof. E. A. Milne, was in the chair, and the discussion was based upon four papers contributed during the recess by the following authors: Mr. H. W. Newton, of the Royal Observatory, Greenwich ("Solar Flares and Magnetic Storms": second paper); Dr. C. W. Allen, of the Solar Observatory, Canberra ("Relation between Magnetic Storms and Solar Activity"); Mr. M. A. Ellison ("Sunspot Prominences: some Comparisons between Limb and Disk Appearances"); and Dr. H. A. Brück, of the Solar Physics Observatory, Cambridge ("On the Distribution of Intensity within the Solar Corona"). Others who spoke during the discussion were Prof. H. H. Plaskett, Prof. W. H. McCrea, Dr. T. G. Cowling and Dr. A. Hunter.

Solar Activity and Magnetic Storms

Opening the discussion, Mr. Newton referred briefly to the findings of his earlier paper, entitled "Solar Flares and Magnetic Storms", recently published by the Society. A solar flare may be described as a small area of the sun's surface which shows the hydrogen line (Hα) in strong emission instead of absorption; many other lines show reversals. but observations are normally made by Hα light with the spectrohelioscope—Hale's instrument, which has contributed more than any other to our knowledge of these phenomena during the last solar cycle. The term 'chromospheric eruption' has been in use hitherto to describe these sudden appearances of bright emission in the sunspot areas, but the term 'flare' seems, in the light of our present knowledge, to be preferable, since the bright emission itself shows no appreciable movement either laterally across the disk or in a vertical direction.

Flares have been observed since 1934 by international co-operation, under the auspices of the International Astronomical Union, and have been classified, chiefly on the basis of area, on a qualitative scale of 1, 2, 3, the last being the largest and most intense. Mr. Newton now selects from these records and from an earlier list by Hale, a total of thirty-seven flares which, by reason of great extent (area comparable with the largest spot-groups), duration or intensity, are judged to be of outstanding importance, and these are designated 3 +.

The collection of data relating to these specially intense flares and their subsequent discussion lead to results which are of the greatest interest to geophysicists. In the first place, it is very significant that, of the thirty-seven flares listed in Newton's table, magnetic storms began within 2·0 days of the flares in no fewer than twenty-seven cases, and two thirds of the associated storms are 'great' storms, having a range at Greenwich in $D \geqslant 1°$, or in H or $V \geqslant 300\,\gamma$. Since, even at solar maximum, great storms are rare events (about 3·2 per year), the total number of chance coincidences of a flare day occurring within 2·0 days of the commencement day of a great storm can be shown to be just *one* for the twenty-eight flares in the central zone of the disk. Actually seventeen such coincidences were discovered. The time interval (storm begins *minus* flare first observed) given by the data is $25{\cdot}7 \pm 1{\cdot}5^h$; but the largest five of the great storms give $20{\cdot}3 \pm 0{\cdot}9^h$, and this difference is considered to be real in view of the probable errors.

The distribution of intense flares over the sun's disk prior to great magnetic storms was next considered, each flare being regarded as a source-point for corpuscular emission. Dividing the flares into 'central zone' (0°–45°) and 'outer zone' (45°–90°) flares, and analysing the data by the 'superposed epoch method', there emerges a much closer association between the central zone flares and magnetic storms than is the case for those in the outer zone. Furthermore, since the magnetic records are necessarily more complete than the solar flare records, it is possible to extend the available data by working back from the records of great storms and postulating intense flares on the sun's disk about one day earlier to account for them: these flares would most probably be located near the largest or most active spot-group present on the disk at the time. Maunder and others have, of course, shown that there is a statistical relationship between the central zone passage of great spot-groups and the greatest magnetic storms. These 'deduced' flares, like the observed flares associated with great storms, are found to favour the central regions of the disk.

The whole body of evidence is consistent with the following general hypothesis: (1) an intense solar flare emits ultra-violet radiation, reaching the ionosphere at the same moment as the Hα emission seen with the spectrohelioscope, and gives rise to the synchronous wireless fade-out and magnetic 'crotchet'; (2) there is a newly formed, cone-shaped corpuscular stream ejected at the time and place of the flare, having a semi-vertical angle as large as 40°, or

occasionally larger; (3) the arrival of this corpuscular stream about twenty-six hours later, reaching the earth in a 'head-on' encounter, is the cause of the great magnetic storm with its incidental auroral effects.

The general results of Newton's second paper show that the close relationship between flare and geomagnetic storm is much less definite when the next intensity class (3) of flare is considered. For flares of medium intensity (2) there appears no appreciable connexion between the dual phenomena. Although it seems that a further step has been made in tracing the solar origin of the more intense magnetic storms, Newton has himself emphasized the fact that the smaller magnetic storms which occur during the minimum of the 11-year solar cycle still remain unrelated generally to visible disk markings. The solar origin of these storms is, however, strongly suggested by their tendency to recur at intervals of a solar synodic rotation, as first shown by Maunder forty years ago.

In Dr. Allen's absence, his paper was summarized by Dr. H. A. Brück. Allen's work provides independent confirmation of Newton's conclusions and the well-established association between great magnetic storms and solar flares. Its main importance appears, however, to lie in the attempt to study the cause of those smaller magnetic storms and disturbances the solar origin of which is betrayed by their 27-day recurrence tendency, but which do not show any correlation with observable solar phenomena. Grouping magnetic disturbances observed over a period of thirty-six years according to their recurrence tendency, Allen seeks correlations between the occurrence of the different types of disturbance and the observation of large sunspot groups. For a shorter period of about four years he has also investigated possible correlations between magnetic disturbances grouped according to their recurrence tendency, intensity and sudden commencement and the observation of solar flares or radio fade-outs produced by such flares.

The results of his investigation lead Allen to the conclusion that the influence of the *M*-regions on the sun (in which the origin of the minor magnetic disturbances is to be sought) is affected by the presence of sunspots in their neighbourhood. When these are within 40° of the *M*-region, they seem to deflect the emitted particles in very much the same way in which streamers in the solar corona are deflected by regions around sunspots. This, and the particular persistence of the *M*-regions or recurrent disturbances one or two years before sunspot minimum when the equatorial coronal streamers have their greatest extension, suggests according to Allen that *M*-regions are identical with coronal streamers. Their base appears to cover an extended region on the sun from which the corpuscular emission is constrained to move in limited streams by forces in the solar atmosphere. Allen's *M*-regions are therefore rather different from the relatively small *C*-regions of abnormal emission in the coronal line λ 5303 found by Waldmeier (1942) and identified by him with the *M*-regions. Further studies of the recurrent disturbances during the present solar minimum might possibly bring a decision in favour of one or other of the two hypotheses.

Prominence Motions

Describing his paper on sunspot prominences, Mr. Ellison remarked that, hitherto, our knowledge of the forms and motions of prominences had been drawn almost exclusively from the study of *elevation* pictures taken at the sun's limb. The principal instruments in use have been the visual eye-end spectroscope, the spectroheliograph, and, within the last decade, the Lyot coronagraph and the interference polarizing monochromator. The monochromator, as developed by Pettit at Mount Wilson Observatory, following up the original suggestions of Öhman, promises to prove the most generally useful where the study of rapid motions in prominence features is concerned.

With the development of the spectrohelioscope by Hale in 1926, there arose the possibility of studying the motions of sunspot prominences in *plan* view upon the sun's surface by light of the Hα line. It was immediately found that direct readings of the line-of-sight velocity of prominence streamers could be obtained, through the Doppler shifts of the spectral lines, while the horizontal movements were being followed. Thus arose the three-dimensional method of attack. The disk appearances, when these prominences are to be seen by absorption against the brighter background of the chromosphere, also provide fuller and more continuous records, with special reference to the state of activity and stage of development of the parent spot-group. The precise location of the prominence filaments and arches in relation to the spots is likewise of considerable importance in any discussion of the causes of their rapid movements. Observations of this kind made during the past 11-year cycle of solar activity have been contributed mainly by the observatories at Greenwich, Zurich and Sherborne, and Mr. Ellison explained that the present paper was intended to summarize these findings and to provide a correlation with the corresponding types of limb prominence.

Most frequent in occurrence are the inflowing filaments of short life which originate in the surrounding chromosphere or in 'coronal clouds' formed above the spot area, move along curved trajectories and finally terminate near the boundary of the penumbra with a mean velocity of inflow of 48 km./sec. Their mean projected length is 61,000 km. and their movements are found to be independent of the magnetic polarity of the attracting sunspots. These filaments are now regarded as being identical with the 'Fleckenkronen', described by Fényi (1891) from limb observations, and with the "Jets and Rockets" of Evershed's memoir of 1917: they are therefore placed under Type III*a* of the Pettit classification (1943).

Complex formations of loops and arches over sunspots are rare, but single and double arches are frequently seen, with the spectrohelioscope, connecting adjacent sunspots of the same group. The direction of motion of the gases is upwards on one side and downwards on the other side of the arch, only one case in thirty-one having been observed where matter was clearly in descent on both sides of the same arch. Because of their Doppler displacements, such objects cannot be recorded in their entirety with the spectroheliograph. The mean distance between the legs of the arches is 43,000 km., and the mean velocities of inflow and outflow are found to be 39 km./sec. and 28 km./sec. respectively. Such prominences are identified with the arches of Type III*b* in Pettit's limb classification, and the directions of motion are again independent of the magnetic polarities of the associated sunspots.

A further type of great interest is the flanking prominence (Type III*c*), often of great dimensions,

the form, growth and decay of which is intimately connected with the life-history of the adjacent spot-group. These exhibit much internal activity, as well as forming external streamers which leave the tops of the prominences to flow horizontally inwards and downwards into the spot area.

Mr. Ellison emphasized that the slender trajectories, perhaps 100,000 km. in length and no more than 5,000 km. thick, have not received any satisfactory explanation or likely parallel in terrestrial physics. They give one the remarkable impression of being semi-permanent conducting paths along which bright condensations follow one another at frequent intervals over a period of several hours. Such motions were first studied in the cinematograph films taken by McMath. In the horizontal trajectories it would seem that gravity must be compensated by radiation pressure, and that the motive force along the trajectory may be of an electrostatic nature. This, however, introduces a difficulty, for the highly conducting properties of the hot solar gases would appear to prevent the collection of electrostatic charges.

Photometry of the Corona

Dealing with his investigation of the intensity distribution within the inner corona, Dr. Brück mentioned that Waldmeier had recently published a paper on the same subject in which he found signs of a connexion between intensity gradients and the structure of the corona. Dr. Brück's photometric work confirms Waldmeier's suggestions in greater detail. It has been based upon a plate which was obtained by the late Prof. H. F. Newall during the eclipse of August 30, 1905, in Algiers, and at the same time as the plate from which Waldmeier's conclusions had been derived.

The distribution of intensity has been determined from records made with a microphotometer along seventy-two solar radii equally spaced in position angle, and the results have been represented by a series of isophotes covering an intensity ratio of mag. 2·5. These are sensibly circular, as is to be expected for an eclipse near sunspot maximum, but show considerable local variations corresponding to the structure of the corona on the original negative. Intensity gradients, when derived for a region extending from a distance of about 2′ to a distance of about 5′ from the solar limb, show systematic variations with position angle in the sense that intensities, and therewith densities of scattering electrons, seem to decrease less rapidly with increasing distance from the sun when measured along rays than in 'normal' regions in between. The opposite effect has been observed by von Klüber for streamers in the outer corona, which extend from about 6′ to about 70′ from the limb.

As a consequence of his own work, Waldmeier believes that the inner corona is composed of a spherical shell of electrons, atoms and ions. The electrons, by scattering light from the photosphere, give rise to the continuous spectrum of the corona. Over the sunspot zones, where the ultra-violet and corpuscular radiations are assumed to be most intense, the atoms are ionized to a very high degree, losing as many as fifteen electrons, and are left in metastable states from which emission of the forbidden coronal lines takes place in accordance with Edlén's remarkable hypothesis. The increased ionization leads in turn to a greater electron density, with the consequent brightening of the continuous spectrum which has been observed in these regions.

KILIMANJARO: AN ACTIVE VOLCANO

By DR. P. E. KENT

IT is nearly a century since Kilimanjaro was discovered, a snow-capped mountain 200 miles south of the equator, and the highest point in Africa. Until recently it was thought to be quite extinct, but expeditions during the last few years have produced evidence of a recrudescence of activity in the broad Kibo crater which forms the more easterly of the twin summits.

Meyer[1], the first explorer to climb the mountain, observed that in 1889 the crater floor was almost entirely covered with weathered ice, commenting "the volcanic activity of Kilimanjaro is now a thing of the past; there is no trace even of fumaroles". He recognized, however, that the local emergence of the rock floor indicated a relic of internal heat.

From the time of the first discovery, however, the amount of ice has been diminishing. In 1889 the crater basin discharged ice through a gap in the western side, but in 1906 discharge had ceased, and there has been no connexion between the crater ice and the glaciers of the mountain slopes since that time. A detailed map by Klute[2] dating from 1912 showed large isolated masses of ice and snow on the crater floor, including a mass practically in the centre, and in 1921 Gillman[3] was able to detail considerable reductions in the ice masses, which he thought might be due to climatic fluctuation. In the next few years further evidence of the reduction was obtained[4], and Mittelholzer[5] published a series of air photographs taken early in 1928 which showed the crater floor mantled with only a thin and patchy covering of snow, and showed a perfectly preserved central crater pit (located where Klute had mapped an "Eisburg") which had apparently not been seen before. Subsequent air photographs show that snow conditions were virtually unchanged in 1932, but that there was a temporary increase in quantity in 1937[6] and that in mid-1942 the greater part of the rock floor was clear[7]. There was thus a rapid decrease in the snow cap in the period preceding 1928, fluctuation during 1928–37, and subsequent further reduction.

H. W. Tilman[8] climbed the mountain in 1930 and 1933. He found the snow on the outer slopes much reduced between the two visits, and in 1933 observed sulphurous fumes and pieces of sulphur in the crater —the first signs of the gas emission which has since greatly increased.

Two years ago, fresh evidence was obtained. J. J. Richard ascended the mountain in the autumn of 1942 and saw several well-developed fumaroles surrounded by sulphur deposits, and found that the rocks were warm in several places[9]. Early in 1943, he climbed the mountain again in company with Mr. Spink of the Meteorological Department of East Africa[10], and found that the number of fumaroles had increased from about six to twenty, and that sulphurous fumes could be detected at some distance. Reports from the western side of the mountain described underground rumbling noises and earth tremors.

Spink[11] has since reported a visit to the crater on July 18, 1943, and a detailed account of the phe-

nomena observed has been published in East Africa[12]. Activity was most strongly developed on the western and southern sides of the crater area, where almost continuous parallel lines of fumaroles were found associated with extensive beds of crystalline sulphur. Emission of sulphurous and acrid-smelling gases was so copious that they could be detected a considerable distance away. The temperature of the fumaroles varied from 52° to 78° F. It was found that parts of the ground were warm and soft, so that the mountaineer frequently sank to his knees: the broken surface gassed freely, and it was clear that the gas emission was by no means confined to the obvious vents.

It is evident from these observations that the fumarole activity is increasing to a considerable volume, and there can be no doubt that the mountain should not be classified as extinct. The central pit in the crater first photographed by Mittelholzer is one of the most perfectly preserved vents in Africa, comparable with the pits in the craters of some of the active Mufumbiro volcanoes in Uganda. It may well have been formed within the last few hundred years, although the presence of a permanent ice cap may have had a protecting effect and the fresh appearance may be somewhat deceptive.

The presence of active volcanoes in East Africa makes one wonder whether there will ever be a recurrence of the great eruptions when enormous areas of the highlands were flooded with lava and covered with layers of volcanic ash. The active volcanoes occur in three widely separated areas: west of Kilimanjaro, the mountain Doinyo Ngai has erupted at intervals during the last fifty years; far to the north in Kenya, Teleki's and Andrew's volcanoes at the southern end of Lake Rudolf have been occasionally active; and in Uganda, Nyamlagira of the active Mufumbiro group discharged a lava flow into Lake Kivu in 1938. In the intervening areas hot springs are known in many places, for example along the shores of Lakes Hannington, Magadi, Natron and Manyara (most commonly on the western shores, for some unexplained reason), and steam jets at Eburru in the Njorowa gorge and in the volcanoes Longonot and Meru show that underground temperatures are still high over a wide area.

It is usually supposed that the localized activity of the volcanoes is a last dying glow, the remnant of the great eruptions which produced the plateau lavas. But there is much geological evidence to show that lavas were produced during two separate periods which were separated by a time of quiescence probably as marked as that of the present day. There may, in fact, be a third upwelling of the lava from below over the highlands of East Africa. If there is, one can be sure that it will develop gradually and—if it happens at all—it is not to be expected until many centuries have passed.

OBITUARIES

Prof. H. F. Newall, F.R.S.

THERE passed away peacefully at Cambridge on February 22, at the age of eighty-six, an astrophysicist of real distinction, who by his personal work in stellar and solar spectroscopic observations and in the design of spectrographs, by his discoveries and by his fine character had a marked influence on astrophysics at Cambridge, both in establishing it as a university study and in attracting younger workers into the field in which he himself had been so notable a pioneer. The first professor of astrophysics at Cambridge, he was a true natural philosopher, who had survived into an era of specialists from a more gracious and spacious age, in which he could study, unhurried, the whole world of Nature and of art.

Hugh Frank Newall was born at Gateshead-on-Tyne on June 21, 1857, a son of Robert Stirling Newall, F.R.S. His mother was the daughter of Hugh Lee Pattinson, F.R.S. R. S. Newall (born at Dundee in 1812) was the head of a considerable firm engaged in the manufacture of wire ropes, which he had himself invented; this firm made the first Atlantic cable, laid by the *Great Eastern*. Pattinson, likewise, had invented a commercial process—the desilverization of lead. R. S. Newall saw two rough disks of crown and flint glass exhibited at the Exhibition of 1862, acquired them and had them made into a lens of 25-in. aperture, which he caused to be erected at Gateshead as part of an equatorial refracting telescope, of focal length 29 ft. Here it was visited by the great and learned of the day. In March 1889—the year in which he died—he offered the telescope to the University of Cambridge.

His son, Hugh Frank, had been educated at Rugby (1872–76) and Trinity College, Cambridge (1876–80) and had then gone as an assistant master to Wellington College (1881–83). The next three years he spent partly abroad, and while he was at Perugia in 1886 an invitation came from the then Cavendish Professor (J. J. Thomson) to become his assistant and demonstrator at the Cavendish Laboratory. This offer coincided with Newall's natural tastes and inclinations and he occupied the post thus offered from 1886 until 1890.

The University of Cambridge was at first not eager to accept R. S. Newall's offer of the big telescope, partly on grounds of expense, partly because of want of a suitably qualified person to take charge. H. F. Newall's own desires were for a career in pure physics, more particularly in spectroscopy—he was much attracted by the inquiries suggested by J. J. Thomson's discovery of the electrodeless discharge through rarefied gases—but he sacrificed those desires and resigned his post at the Cavendish in order to supervise and indeed operate the Newall telescope. It was more than a sacrifice of personal inclination: he not only became henceforward a worker without stipend, but also he paid for the expense of removal of the Newall telescope from Gateshead to Cambridge out of his own share of the family patrimony. From 1891 onwards he was the Newall Observer, and in 1904 he became assistant director of the Cambridge Observatory under Sir Robert Ball. The first "Report" on the proceedings with the Newall telescope was dated 1892. His first paper in the *Monthly Notices of the Royal Astronomical Society* appeared in 1894, entitled "Notes on some Photographs taken with a Visual Telescope". Papers on astrophysics

followed in a regular stream. He never, however, relinquished his original interest in spectroscopy for spectroscopy's sake, and he had the honour of a paper in the first volume (1895) of the *Astrophysical Journal*, on the spectrum of argon, then newly discovered by Ramsey and Rayleigh.

Newall's first thoughts, on being put in charge of the Newall telescope, were to adapt it for photographing and measuring the spectra of the stars. He began by constructing a one-prism spectrograph (the Bruce Spectrograph) for attachment to the eye-end. This, it is interesting to recall, was named after an American benefactor who gave funds for such instruments. It was in action in 1895. Newall also added a correcting lens to the 25-in., to obtain an improved colour curve in the photographic region. The description of the Bruce Spectrograph was published in the *Monthly Notices* of 1896, and reprinted in the *Astrophysical Journal* (Vol. 3) for the same year. With this, and more especially a later four-prism spectrograph which he also designed and put into use in 1899 (though he did not formally describe it until 1905), Newall began systematic observations on the radial velocities of the stars, through the Doppler effects in their spectra. For the accurate determination of wave-lengths in stellar spectra, an iron arc comparison spectrum was used. To astrophysicists of the present generation, this may seem a routine matter. But anyone who reads W. W. Campbell's "Stellar Motions" will appreciate the difficulties that dogged the footsteps of the early measurers of stellar wave-lengths, when striving for an accuracy sufficient to give an error of only a few km. per sec. in the line of sight velocity. There were difficulties due to flexure of the tubes of telescopes when heavy spectroscopic apparatus was clamped on to them—apparatus for which they had not been designed. There were difficulties due to temperature variations. There were difficulties with the production of a comparison spectrum which had to be formed from the same slit, and to be derived from the same spectroscopic train, as the light from the star. There were difficulties even in viewing the stellar image sufficiently clearly to afford accurate guiding. All these, Newall with his own unaided instrumental good sense and sound principles of optical design, and his consummate skill with his hands, triumphantly overcame. He deserves the greatest possible credit for his pioneer work in this field. Newall showed that high-precision stellar spectroscopy was possible, and possible in Great Britain. Without Newall's devotion to a subject not of his own choosing, without his sacrifice of the career in physics which was opening before him, Great Britain would have lagged behind the work then being done by Vogel at Potsdam and Campbell at Lick.

The fruits of this work appeared in 1899 when Newall announced (*Mon. Not.*, 60, 2; 1899) his discovery that the star α Aurigæ (Capella) was a spectroscopic binary; the same discovery was made simultaneously and independently by W. W. Campbell at Lick. Newall's substantive paper "On the Binary System of Capella" appeared in 1900 (*Mon. Not.*, 60, 418; 1900).

Meanwhile Newall had been gaining experience as a solar observer. He took part in an expedition (with E. H. Hills) to Pulgaon, India, to observe the total solar eclipse of Jan. 22, 1898; and in an expedition to Algiers for the eclipse of May 28, 1900. There was also the expedition to Sumatra for the eclipse of May 17–18, 1901; and we may mention here the expedition to Guelma (Algeria) for the eclipse of Aug. 30, 1905, at which he obtained a splendid photograph of the solar corona (a slide of which, by an apt coincidence, was thrown on the screen in the course of a discussion at the same meeting of the Royal Astronomical Society as that at which his death was announced; see p. 454 of this issue). His later expeditions, to the Crimea (eclipse of Aug. 20–21, 1914) and to Norway (June 29, 1927), were frustrated by weather.

Newall's work was recognized by his election to the Royal Society in 1902. During 1905–7 solar instruments were purchased out of the Frank McClean Bequest, and added as an annexe to the Newall dome. These included a 16-in. cœlostat and a 14-ft. plane-grating spectrograph of Littrow type, producing a 6-in. solar image. Again, in 1908 the Royal Society offered the Huggins telescopes from Tulse Hill (a 15-in. refractor and an 18-in. reflector on the same mounting) to the University of Cambridge, and these came under Newall's care in 1909. He was president of the Royal Astronomical Society during 1907–9.

This period of Newall's most intense activity was fittingly crowned by his appointment in 1909 as professor of astrophysics at Cambridge (without stipend) and his election as a fellow of Trinity. In 1911, on the retirement of Sir Norman Lockyer from the directorship of the Solar Physics Observatory at South Kensington, it was decided to transfer that observatory to Cambridge; and in April 1913 the move was effected. Henceforward the old Solar Physics Observatory was fused with the Astrophysics Department and the Newall telescope, and, under Newall as director, the combined Solar Physics Observatory left the control of the University Observatory. Newall held the posts of professor of astrophysics and director of the Solar Physics Observatory until 1928, when he retired and was succeeded by Prof. F. J. M. Stratton, who had been formerly one of his assistant directors. It is understood that the chair was endowed through the generosity of Newall.

Newall observed the spectrum of Nova Aquilæ in 1918. In 1916 he had identified (with F. E. Baxandall and C. P. Butler) the *G*-band in the solar spectrum with a band due to hydrocarbons. Later he occupied himself with problems of solar rotation and the relations between successive spot-cycles, and he devised a promising method for obtaining differentially the departures of the law of rotation of the sun from that of a rigid body.

Newall was an honorary D.Sc. of Durham, a foreign member of the Spectroscopisti Italiani, and a collaborator on the editorial board of the *Astrophysical Journal*. In 1925, he was a vice-president of the International Astronomical Union for its Cambridge meeting.

Newall married, first, in 1881, Margaret, daughter of the Rev. A. T. Arnold, a house-master of Rugby. Mrs. Newall was an experienced eclipse-observer, accompanying Newall on all his expeditions. She died in 1930. He married, secondly, in 1931, Dame Bertha Surtees Phillpotts, sometime head of Westfield College and mistress of Girton. She died in 1932.

Newall was something very much more than the sum of his published papers, or the bare record of his activities. All who came in contact with him recognized him as a man for whom science stood for something large and gracious, a mistress to receive court, to be adorned in lovely garments, not to be soiled by grim contacts with grim workaday life, to hold converse with at leisure, to be reverenced with

serenity. As I have already written and must write again, he was a true natural philosopher, of a kind, I think, more common in the last century than this, to whom curiosity about Nature on the broadest scale was the overmastering motive. In the Newalls' home at Madingley Rise, Cambridge, one heard science talked about in a queenly way, as an intrinsic part of the good life, in partnership with art and music. Sooner or later one met at the Newalls' everyone who counted in astrophysics and the allied parts of physics, and a dinner there was a true meeting of minds, where thoughts could be exchanged on a new phenomenon, a new flower, some development in farming, a Stonehenge discovery or a new star. Newall was the friend of Huggins, Michelson and Hale, and in his knowledge of optical design not their inferior. He was the friend, too, of many younger workers in astrophysics, who received from him hospitality, a captivating welcome and much sound sense as to the directions their energies should take. Withal he was a conservative, loth to embrace modern theories, seeing Nature rather as a complicated spectacle of phenomena than as a stamping-ground for principles. He belonged to the disappearing school which thought that insight into the phenomena apparent in the stars could be gained by consideration of simple laboratory experiments.

Newall was the most modest of men, never referring to his own achievements. Although generally unreserved in his conversation, he clung to reticence about deeper things as to the dress of decency. He was generous in praise of others, and generous and self-sacrificing in all matters of personal conduct. How he would have hated the thought of this his obituary being written! His distinguished personal appearance was the index of a true distinction of mind. We shall long mourn one of the fathers of astrophysics in Great Britain. E. A. Milne.

Dr. J. McKeen Cattell

Dr. J. McKeen Cattell, for the past fifty years editor of *Science*, the weekly journal of the American Association for the Advancement of Science, died in January, aged eighty-three, at Lancaster, Pennsylvania. He was long known as the "dean of American science", although his own subject strictly was psychology. In concurrently editing various periodicals his industry was immense; but he won renown no less as teacher, research worker, and compiler of scientific reference books.

Son of the president of Lafayette College, also in Pennsylvania, Cattell after taking his degree there in 1880 went to study in Göttingen, Leipzig, Paris and Geneva, then returned to Leipzig to gain his Ph.D. in 1886. Two years thereafter he was lecturing in Cambridge, during which time he married Miss Josephine Owen, of London. Psychology as a separate study was in those days in its early development in the United States under Prof. William James of Harvard, and when Dr. Cattell received a call from Philadelphia, to fill a similar chair in the University of Pennsylvania, he went home to his career. In 1891 he proceeded to Columbia University, New York, where for twenty-six years he taught both pupils and teachers, engaging at the same time in researches upon measurement of behaviour, individual and group differences, measurement of psychophysical time, intensity and extensity, perception, fatigue, memory, and association of ideas.

Within about ten years after assuming the editorship of *Science*, Cattell began to edit also *The American Naturalist*, devoted to the biological sciences, and compiled the first edition of his "American Men of Science", a "Who's Who" of research workers. (This book, now grown to 28,000 names, unfortunately and surprisingly lacks a subject-index, and the same is true of its companion volume, "Leaders in Education", first published in 1932.)

Cattell was always a man who pertinaciously stuck to causes or views which he believed in, regardless of what might happen to himself therefrom. In October 1917, six months after the United States had entered the War of 1914–18, he wrote to various members of Congress "not to require drafted men to fight in Europe against their will". For this he was dismissed from his professorship at Columbia. Was such dismissal, when the United States was at war, a violation of academic freedom? Eminent colleagues of Cattell's, Prof. John Dewey the philosopher, and Profs. James Harvey Robinson and Charles A. Beard the historians, protested furiously, and Prof. Beard resigned. Cattell later explained that he meant his letter to apply to conscientious objectors only; but he was not reinstated. Having been a member of the staff for a quarter of a century, Cattell then applied for his pension. It was refused him. Whereupon he sued the University for 150,000 dollars. The case was settled out of court by the award to Cattell of 45,000 dollars.

But by this time Cattell was so deeply occupied in editing his various publications that the loss of his post made little difference to him except to give him several additional hours per week to edit still others. Even while the last War was being fought out he began, from an office in the high tower of Grand Central Terminal, New York, to edit *School and Society*, which in the twenty-five years of his direction grew to be perhaps the leading educational journal in America. Longer still—forty years—was his tenure of the editorial chair of *The Scientific Monthly*, and during a critical period he presided also over *Popular Science Monthly*. In these multitudinous activities two of Cattell's four sons ably assisted him, and survive to carry on a considerable proportion of his work.

If, as some have said, there is in the United States no such thing as a school-leaving age, the gospel of unlimited educational opportunity owes much to the preaching of it by Cattell. But, completely enveloped in science as he was, he tended to attribute to it all the blessings of America and none of the difficulties. "The industrial applications of science," he said in one of his prefaces, "have quadrupled the productivity of labour, abolished slavery, the subjection of women, and child labour, and have made possible universal education even to the age of 18 or 20."

In his long career Cattell was chosen president of many learned societies, including the American Association for the Advancement of Science, nor did his stand in the War of 1914–18 deter the French from electing him a Commander of the Legion of Honour. Willard Connely.

We regret to announce the following deaths:

Prof. Karl Schuchhardt, formerly director of the Prehistoric Department of the Folk-Lore Museum in Berlin, aged eighty-four.

Dr. C. H. Townsend, director during 1902–37 of the New York Aquarium, on January 28, aged eighty-four.

NEWS and VIEWS

Committee on Technical Education

MR. BUTLER, President of the Board of Education, has announced in a Parliamentary written answer that the following have been appointed members of a departmental committee to report on higher technological education in England and Wales: Lord Eustace Percy (*chairman*), Dr. D. S. Anderson, Sir Lawrence Bragg, Mr. W. H. S. Chance, Sir Charles Darwin, Dr. E. V. Evans, Mr. B. Mouat Jones, Mr. S. C. Laws, Dr. H. Lowery, Mr. H. S. Magnay, Sir George Nelson, Mr. J. F. Rees, Dr. R. V. Southwell, Mr. H. Fitzherbert Wright, with Mr. Maxwell-Hyslop, Board of Education, as secretary. Officers of the Board of Education will attend meetings of the committee as assessors.

The terms of reference of the Committee are: "Having regard to the requirements of industry, to consider the needs of higher technological education in England and Wales and the respective contributions to be made thereto by universities and technical colleges, and to make recommendations, among other things, as to the means for maintaining appropriate collaboration between universities and technical colleges in this field."

Application of Research in Industry

IN his address "The Application of Research" to the Manchester Chamber of Commerce on March 31, Dr. Andrew McCance said that we should not think of research merely in terms of great laboratories equipped with intricate and expensive apparatus and staffed by scientific wizards aloof from mundane affairs. Valuable information can often be obtained with the simplest equipment, and scientific men are ordinary men whose judgment has been trained to exclude prejudice and to accept only those conclusions which are supported by facts. As example, he referred to investigations on temperature variations in blast furnaces, which have led to a great increase in regularity of output and a corresponding economy in coke consumption. The structure of a research association depends on the organization of the industry. With an industry such as the iron and steel industry, in which the main production comes from a number of large units, each unit can usually make a material contribution to the common cause by undertaking in its own research department a share of the investigations required into a specific problem. Recently, however, this industry has decided to form a new research association, and in future finance for research within the industry in Great Britain will be obtained by a voluntary levy on the ingot production of all producers in the federation. All the work is controlled by a number of committees, dealing with such subjects as blast furnaces, rolling mills, alloy steels, corrosion, etc., and Dr. McCance referred in particular to the work of the Hair Line Crack Committee dealing with the minute cracks which occur in high tensile alloy steel and their prevention, as illustrating the potentialities of co-operative research. This investigation was founded on an effective scheme of co-operation between industrial and university research laboratories.

Research, Dr. McCance emphasized, begins with an attitude of mind, and it is essential first to create the correct attitude of mind in staff and throughout the organization. The research department then becomes an integral part of the production department, planning ahead continually for the creation of new products, new processes and new economics. It is during the initial stage of employing a nucleus of scientifically trained men to create standards for raw materials and products and to investigate faults in manufacture and processes that sympathetic understanding and guidance are most required if antagonism and friction are to be avoided. When the department becomes an accepted part of the organization, additional staff is required to take over the routine work, and the original staff can begin to tackle the more fundamental problems of research-controlled development. Technical control of a business requires the employment of men who have received a technical training. No business can be made more scientific from outside, and Dr. McCance does not believe that a scientific training makes men less practical in their outlook. It is the waste of latent abilities through lack of opportunity or training that should give us more concern, and industry must co-operate in the development and utilization of training facilities if the future supply of competent executives and research workers is to be assured and the enterprise of British industry maintained.

Editorship of *British Birds*

THE place of the late H. F. Witherby, who so successfully conducted *British Birds* through thirty-six volumes, has been taken by Bernard W. Tucker, in accordance, it is understood, with Mr. Witherby's wishes. With Mr. Tucker will be associated in the editing of the journal, Dr. Norman F. Ticehurst and Major A. W. Boyd. *British Birds* has been assiduous in publishing about birds in Britain items of information many of which would otherwise have been lost to record, but it has played a more important part in encouraging scientific observation of bird-life and in suggesting problems and, by example, showing how problems may be tackled. In January 1917, *British Birds* incorporated *The Zoologist*, and thus disappeared after a long and useful history the only magazine which published notes on any aspect of British natural history from any part of Great Britain. The *Scottish Naturalist* performed a similar duty for the northern part of the kingdom, but it is a war casualty. The result is that there is now no magazine available for recording the minor observations of British naturalists on subjects other than birds, so that the cumulative value of the work of that great band of amateur observers, for which Great Britain has long been noted, is being lost. Is it too much to hope that when the War is over a *British Naturalist* will arise, wherein the ordinary student of Nature will be able to put on record field notes of casual interest and articles of connected observations?

Stereoscopic Photographs: 'Polaroid Vectographs'

INFORMATION recently released about the 'Polaroid Vectograph', a system of stereoscopic photography developed by the Polaroid Corporation, reveals that the method is playing an important part in war-time aerial photography. A short account of the underlying principles was given by E. H. Land in 1940 (*J. Opt. Soc. Amer.*, 30, 230; 1940). As in all stereoscopic systems, two photographs of a scene taken from different positions have to be presented to the observer so that the picture taken from the right is seen by the right eye, while that from the left is seen by the left eye. In the 'Vectograph', two very thin polarizing surfaces are located immediately above

an aluminized surface and are oriented so that the vibration directions of the two layers are crossed relative to one another. The light and shade of the 'left' image is controlled by the number of submicroscopic crystals in one of the layers, and that of the 'right' image by the crystal distribution in the other layer. The 'left' image is seen by the left eye through a 'Polaroid' filter placed in front of the eye to act as analyser, the vibration direction of the analyser being crossed with respect to that of the 'left' image. The white areas of the image are thus represented by regions where the polaroid crystals are absent, and the blacks by areas of maximum concentration; further, since the left-eye analyser is parallel relative to the vibration direction of the 'right' image, the presence or absence of crystals in the latter have no effect on the appearance of the 'left' image. A similar viewing arrangement is used to enable the right eye to see the 'right' image.

The result is startlingly effective. The simplicity of the viewing equipment and the approximate superposition of the two images make fusion a matter of no difficulty whatever. When the original photographs are taken from an aircraft, the distance apart at which they are taken can be made large to give the effect of an exaggerated interocular distance. This leads to a greatly enhanced stereoscopic effect which can obviously have very important applications.

Chemical Laboratory Planning

The design of modern industrial chemical laboratories has been dealt with recently by E. D. Mills (*J. Roy. Inst. Brit. Architects*, 51, No. 2, 27; Dec. 1943). The article, although short, contains some useful details and illustrations, with a short bibliography, and should be useful to those responsible for the erection and equipment of chemical laboratories. Further information about such matters as ventilation (which is quite different from that for normal buildings) would have made it more informative and practical. Many architects have very little idea of what is required, and actual figures are not easy to find.

Ancient Astronomy

A series of articles entitled "Man and His Expanding Universe" is appearing in *Sky and Telescope*, the first of which, in the December issue, deals with Egyptian astronomy. As the life of the Egyptians depended on the overflowing of the Nile, the beginning of which occurred near the time of the summer solstice, the priest-astronomers held a very high position because they knew that the solstice took place about the time of the helical risings of certain stars. Owing to the precession of the equinoxes, the same star could not be used indefinitely, and it is possible to correlate the times of the buildings of some of their temples with our modern calendar, by calculating the times of the helical risings of some of the principal stars. The solar temple of Amen-Ra at Karnak was so oriented that at the summer solstice the setting sun was able to shine through the entire length of the temple and illuminate a golden image in the sanctuary, and the worshippers saw, not the image itself, but "the presence of the god Ra himself in the sanctuary".

The subject is continued in an article in the January issue of *Sky and Telescope* which deals with Chinese and Babylonian astronomy, in so far as a knowledge of the subject was applied to the orientation of temples. Reference is also made to Solomon's Temple, which was so oriented that the rays of the rising sun at the spring and autumn equinoxes penetrated to the Holy of Holies and were reflected by the jewels of the high priest. The basilica of St. Peter's, Rome, is placed due east and west, so that the rays of the rising sun at the vernal equinox can illuminate the high altar at the end of the nave. These articles present many interesting features and explain the orientation of public buildings thousands of years ago when astronomical knowledge was often deliberately concealed from the people, thus enhancing the prestige of the priest-astronomers.

Poliomyelitis in Chile

According to a recent official report, only 99 cases of poliomyelitis were observed in Chile during the period 1937–41. 84 of the cases occurred in children less than two years of age, and only one in the age group 5–10 years. No case was observed in persons above ten years of age. Of the 99 cases, 98 showed motor weakness of the lower extremities, and in 11 the paralysis involved the upper extremities also; in one third of the cases the paralysis was bilateral.

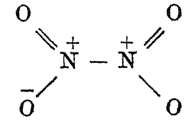
Institute of Physics: Australian Branch

Prof. A. D. Ross, professor of physics in the University of Western Australia, has been elected president of the Australian Branch of the Institute of Physics. The previous presidents have been Prof. T. H. Laby of Melbourne and Prof. Kerr Grant of Adelaide. Dr. Ross has been local honorary secretary of the Institute in Australia for some twenty years, and he was the first to suggest the formation of a branch of the Institute in Australia. The Branch now includes more than 120 fellows and associates, apart from subscribers and students, and active divisions meet regularly during the year in Melbourne, Perth and Sydney.

Pharmaceutical Scholarships for Chinese Students

The Pharmaceutical Society of Great Britain announces that five pharmaceutical manufacturers have each agreed to give scholarships to enable pharmaceutical graduates from China to take a two years course at the University of London. They would then return to China to help to train the 50,000 pharmacists required for General Chiang Kai-shek's ten-year plan for public health services. The donors of the scholarships are Messrs. Allen and Hanburys, Ltd., London; Messrs. Boots Pure Drug Co., Ltd., Nottingham; Messrs. Evans, Sons, Lescher and Webb, Ltd., Speke, Liverpool; The Wellcome Foundation, Ltd., London; and Messrs. May and Baker, Ltd., Dagenham. The suggestion for such scholarships came from Mr. A. H. Bentley, a pharmacist who escaped from the Japanese in Hong Kong. It is expected that the cost of each scholarship will be £1,400.

Erratum. In the communication by H. C. Longuet-Higgins in Nature of April 1, p. 408, formula (iii) should read



The term "nitrogen tetroxide" should have been used throughout, instead of "nitrogen peroxide".

An Antibiotic from *Aspergillus parasiticus*

RECENTLY we had occasion to examine the possible production of antibacterial materials by about twenty strains of *Aspergillus flavus*, *A. oryzæ*, *A. tamarii* and *A. parasiticus*. The culture fluids showed no significant antibacterial titres when a medium of the Czapek type was used; the test organism was *Staphylococcus aureus* and both the serial dilution method and the plate test[1] were used. When the medium contained bactotryptone or 7–8 per cent of corn-steep liquor together with 4 per cent of glucose and inorganic salts, several of the strains of *A. flavus* and *A. tamarii* produced culture fluids which were weakly antibacterial, being completely inhibitory at dilutions of 1 : 30–80 after 5–14 days incubation at 22–24°. Far superior were the filtrates obtained from four strains of *A. parasiticus*, which gave titres of complete inhibition of 1 : 200–600 after 5–12 days at 24°. A concentrate of the product of one of these four strains was obtained by absorbing the antibacterial principle on charcoal and eluting with aqueous acetone, 50 per cent of the activity being so recovered.

It was later found that in presence of corn-steep liquor additional inorganic salts were unnecessary for the production of antibacterial activity, though copper (1 : 100,000) had a very marked effect on the growth of *A. parasiticus*: with added copper the mould grew luxuriantly with rapid formation of olive-green spores; in its absence, growth was less vigorous and the mycelium remained lemon-yellow for the whole period of growth (up to 14 days). Even added carbohydrate was unnecessary, for the full antibacterial titre developed in 7·5 per cent corn-steep liquor adjusted to pH 7 (the sample of liquor contained a small amount of fermentable carbohydrate). Experiments on the length of incubation using varying amounts of glucose in the culture medium threw some light on the probable reason for the apparent superiority of *A. parasiticus* over *A. flavus*. The former grown in 7·5 per cent corn-steep liquor with 0·5 per cent additional glucose produced maximum antibiotic activity in 4–5 days; the antibacterial titre decreased after 7–8 days though appreciable activity was still present after incubation for one month. With two strains of *A. flavus*, however, activity was markedly more transient, and in one case had disappeared on the ninth day of incubation. The glucose content of the medium had a pronounced effect on the *rate* of production of activity by both species. In cultures of *A. parasiticus*, addition of 2 per cent of glucose (compared with 0·5 per cent of glucose) caused a delay of 48 hours in the production of similar activity, the maximum being reached only on the eleventh day. *A. flavus* cultures showed a similar time-lag, and in addition the maximum activity attained was considerably less in 2 per cent or 5 per cent of glucose than in 0·5 per cent of glucose; indeed, with one strain of *A. flavus* appearance of activity was completely suppressed when 5 per cent of glucose was used.

The products from all the strains of *A. parasiticus* grown with or without additional glucose or salts lost all activity on standing at pH 2 for 30 min. or at pH 11 for 30 min. The active material was extracted by ether, chloroform, or amyl acetate from aqueous solution at pH 2–3, and was recovered in aqueous solution by shaking the extract with a suspension of barium carbonate. The antibiotic was approximately as active against *B. fascians* (a Gram-positive plant pathogen) as against *Staph. aureus*, but was inactive against *B. coli*, *B. pyocyaneus*, *B. prodigeosus* and several other Gram-negative bacterial species.

In both chemical and antibacterial properties the new antibiotic resembles penicillin. Antibiotics of similar character have also been obtained from strains of *A. flavus* in surface[2] and submerged[3] culture and from *A. giganteus*[4], so that the production of such materials is evidently more generally possible than has been supposed. The antibacterial titres obtained from at least one strain of *A. parasiticus* are sufficiently high to make its culture of possible practical value. There is insufficient evidence to decide the identity of penicillin or other Aspergillus products with that from *A. parasiticus*, and it is provisionally proposed to designate the new product 'parasiticin'.

We thank Prof. I. M. Heilbron for his encouragement and the Rockefeller Foundation for financial assistance.

Trypan Blue and Growth of the Adrenal Cortex in Mice

ACCORDING to a recent communication, Calma and Foster[1] have been unable to demonstrate centripetal cell migration in the adrenal gland of the rat by the use of trypan blue. Salmon and Zwemer[2], using the same vital stain, had previously reported inward cell movement. These last-mentioned workers injected the dye subcutaneously and found it taken up first by the cells in the capsule and after varying intervals by cells of the glomerulosa, fasciculata, and reticulosa successively, while the outer layers became dye-free.

More than two years ago, while I was working on the X-zone of the mouse, adrenal experiments similar to those of Salmon and Zwemer were started but discontinued with the publication of their report. The appearance of Calma and Foster's letter prompted a re-examination of old slides and a study of more mice. In one experiment five animals received ¼ c.c. of 1 per cent trypan blue for two days, and then left and right adrenals were examined separately after intervals of approximately six days; thus each animal served for two observations. The last adrenal was removed sixty days after the termination of injections.

Inspection of histological preparations of these glands supports the findings of Calma and Foster, namely, that this method yields no evidence of inward cell migration in the adrenal gland. Dye was present in the capsule of every gland, and in greatest amount (to judge by granular size) in the region of the glomerulosa and outer fasciculata.

Goldman[3], in 1909, reported blue granules in the majority of the cortico-adrenal cells of animals receiving excessive amounts of trypan blue. This was clearly demonstrated in one animal sacrificed after 28 successive injections of ½ c.c. of 1 per cent dye. Granules were found not only in all areas of the cortex but also in the cells of the medulla. Thus it would appear that the capsule, glomerulosa and outer fasciculata preferentially store the stain, but that when an immoderate quantity is supplied to the organ the other cells are called to aid in the storage process.

Microbiological Assay of Riboflavin

Experiments in these laboratories using *Lactobacillus helveticus* for riboflavin assay by the method of Snell and Strong[1] have brought to our notice the importance of the temperature of incubation of the cultures.

Position in Incubator	Front						Middle								Back
Tube No.	1	3	5	7	9	11	13	15	17	19	21	23	25	27	29
ml. 0·1 *N* NaOH	3·4	3·55	3·6	3·95	4·05	4·15	4·9	4·45	4·15	3·85	3·75	3·75	3·7	3·65	3·55
Tube No.	30	28	26	24	22	20	18	16	14	12	10	8	6	4	2
ml. 0·1 *N* NaOH	3·5	3·7	4·0	4·0	4·2	4·15	4·55	4·25	4·3	3·85	3·65	3·8	4·05	3·95	3·7

Snell and Strong, and other authors of *L. helveticus* assay methods, advise that the cultures should be incubated at 37° C. We have found, however, that a somewhat higher temperature, in the neighbourhood of 41°–42° C., results in a considerable increase in acid production with a given sub-optimal dose of riboflavin. This is in accordance with Bergey's[2] statement that the optimum temperature for this organism is 40°–42° C. The decreased growth-response resulting from a deviation of 4°–5° C. from this optimum is appreciable and may easily be of the same order of magnitude as that produced by a 25 per cent decrease in riboflavin concentration. (The actual figure depends, of course, on the slope of the dose-response curve in a given experiment, and in cases where this is unusually flat a much higher figure is obtained.)

This observation, which so far as we are aware has not hitherto been reported, is not merely of theoretical interest. Indeed, we have found that the somewhat uneven distribution of temperature in an ordinary bacteriological incubator is sufficient to affect seriously the uniformity of response obtained in a series of identical tubes each containing a sub-optimal dose of riboflavin. The accompanying table shows the titration figures obtained when a series of identical tubes of medium, each containing 0·075 γ riboflavin per 10 ml., was placed in two adjacent rows across the middle of the incubator from front to back; the temperature indicated by the incubator thermometer was 37° C.

It will be seen that the tubes in the middle of each series have, in general, given much higher titration figures than those at the ends. The results are explained by the fact that in this particular incubator the front and back are cooler by some 3°–4° C. than the middle. Similarly, the sides of the incubator are hotter than the middle. The existence of such temperature gradients will not only influence the consistency of replicate tubes, but also the slope of a dose-response curve will obviously be affected by the position of the series in the incubator.

Ideally it is desirable that an incubator for this work should maintain a perfectly even temperature throughout. If this cannot be realized by the use of an internal fan or otherwise, the temperature effect can and should be allowed for in the calculation of the results of assays. Using the latter procedure, the re-calculated results are found to be much more uniform than the uncorrected figures, and the method becomes one of precision. Fiducial limits of 95–106 per cent ($p = 0·95$) have been obtained when five tubes were used at each of five levels of standard and four of unknown. On this basis, 83–120 per cent fiducial limits could be obtained with a total of eight tubes (four standard, four unknown).

The basis of these assay methods is that the vitamin under test should alone be the limiting factor influencing growth. It seems, therefore, that unless *either* stringent precautions are taken to ensure uniformity of incubation temperature, *or* appropriate allowances made for non-uniformity, errors of appreciable magnitude may be introduced. On the other hand, the application of statistical treatment appropriate to the conditions renders the method one of high precision.

Further work is in progress and will be reported more fully in due course. We are indebted to Mr. E. C. Fieller for the statistical analysis of our results.

Mathematics of Biological Assay

D. J. Finney observes[1], in effect, that the data of a four-point assay in which the apparent response curves are not parallel do not allow us to distinguish between two conceivable causes of non-parallelism, namely, (1) non-linearity of the fundamental response curve, and (2) real dissimilarity between the response curves of standard and test material; and that while the first does not invalidate the assay[2,3], the second does. To this we may add that the smaller the difference between the overall mean responses to standard and test material the more reason there is to attribute non-parallelism to the second cause. The whole matter is particularly relevant to the vitamin A assay, which employs a non-vitamin A standard and in which there are therefore no "strong *a priori* reasons for believing that the standard and test

preparations have response curves of identical form"[1]. In this laboratory, statistical check is kept on the difference between the constants of slope for standard and test material (which is equivalent to a check on the value of T, as defined by Finney). No significant deviation has, in fact, been found, but it cannot be assumed that this would apply to other regimes.

Finney's formula for the exact fiducial limits of M, the log dose-ratio between standard and test material, is algebraically identical with that recently discussed by Irwin[4], and its importance is perhaps not widely enough realized. May I suggest a version that is fairly simple to handle ?

Adopting Finney's notation, we may write the fundamental formula for M as

$$d\,\frac{S \pm t_S\varepsilon_S}{R \pm t_R\varepsilon_R}, \quad . \quad . \quad . \quad . \quad . \quad . \qquad (1)$$

using separate t's and ε's because in practice R and S are often based on different numbers of animals. The limits of error alone may be written, in approximation,

$$\pm\, d\,\frac{S}{R}\sqrt{\left(\frac{t_S\varepsilon_S}{S}\right)^2 + \left(\frac{t_R\varepsilon_R}{R}\right)^2}. \quad . \quad . \quad . \qquad (2)$$

Now if the standard error of the slope is more than 13 per cent (that is, if $\varepsilon_R/R > 0{\cdot}13$) this approximation is insufficient, and each R in (2) must be replaced by $\sqrt{R^2 - t^2_R\varepsilon^2_R}$. The mid-point of the resultant, wider, error range then shifts to

$$d\,\frac{S(R^2 - 2t^2_R\varepsilon^2_R)}{R(R^2 - t^2_R\varepsilon^2_R)},$$

although, of course, dS/R still best expresses M.

Age of the Saline Series in the Salt Range of the Punjab

OF all the debated questions of Indian geology there has been none so baffling as the age of the Saline Series in the Punjab[1]. The selected references cited will give an idea of the controversy that has raged round the question, still by no means closed. Two main theories are now in the field : (*a*) that in the eastern part of the Salt Range the Cambrian sequence, with the Purple Sandstone at its base, lies 'normally' over the Saline Series, which therefore must be Lower Cambrian or pre-Cambrian[2] ; (*b*) that the Saline Series is of early Tertiary age and that its inferior position is due to an immense overthrust of post-Nummulitic date which has pushed the older beds bodily over it[3].

Fossils found in the Saline Series in recent years have repeatedly suggested that the beds are early Tertiary or even younger. But the value of this evidence has been questioned : either the specimens were found on scrutiny to be indeterminable or serious doubts arose as to their having been found *in situ*. It has been rightly argued that in such a highly soluble and plastic substance as the Salt Marl, extraneous material might easily have penetrated through solution holes or have been enveloped during relatively modern earth movements, of which there is ample evidence[1]. In view of these objections, I collected, during a recent visit to Khewra (October 5, 1943) and to Warchha (October 14), some lumps of rock-salt with intercalated thin laminæ of saline earth or 'kallar' from positions deep within the salt mines, with the view of examining the kallar for possible microfossils. Here the kallar lies closely interlaminated with the salt, in beds which run continuously for long distances and which, although often highly tilted, show no other visible signs of disturbance. If, as Christie[5] has shown, these saline deposits are a product of normal sedimentation from salt lakes or lagoons, and if these lakes were exposed to the air at a period when land vegetation existed in any degree of profusion, we might reasonably expect to find, among the dust that blew on to the water's surface or in the material that was washed in, at least some microscopic specks of organic matter giving a clue to the life of the period. Further, as between the Cambrian and Tertiary, it should be easy to clinch the matter over a single such speck found *in situ*, provided only that it could be referred to a known group of land plants.

In quest of such a clue I examined a dozen specimens, some collected, as stated, by myself from different places in the mines (with the kind permission of Mr. C. Phillips of Khewra and Mr. B. S. Lamba of Warchha), others kindly sent me last December by Mr. Lamba from the Warchha mine. The order of thickness of the kallar bands in the specimens examined is indicated by the following examples : 1·5 mm. (thinnest), 9 mm., 12 mm., 22·5 mm. (thickest). There is no question here of any cracks or solution holes, nor of any foliation imposed by thrusting or shearing forces such as Dr. Murray Stuart (*loc. cit.*) advanced in explaining the laminated appearance of these deposits.

The investigation of this material has given results beyond all expectation : the bands of kallar must be teeming with signs of life, for every single piece has yielded microfossils. These specks readily float up to the surface where they can, as a rule, be picked out at once by stabbing the film of water with a needle dipped in safranin, which rapidly spreads out and stains all organic fragments. The great majority are undeterminable as to genus and species, being mainly shreds of angiosperm wood, but there are also gymnosperm tracheids with large round bordered pits, and at least one good, winged, six-legged insect with compound eyes. These facts suffice to prove that the Salt Marl of the Punjab cannot possibly be Cambrian or pre-Cambrian as suggested, among others, by Dr. Murray Stuart, Sir Cyril Fox, and now also by Mr. E. R. Gee, until recently a strong advocate of the Eocene view. So, after all, it turns out that the position of the Saline Series beneath the Palæozoic sequence can only be explained, as was first pointed out by Koken and Noetling more than forty years ago (long before we knew any fossils from the Marl), by postulating an overthrust fault of great magnitude.

The main facts here briefly recorded were discussed in a recent address at Hyderabad Deccan[6], where also some of the fossils found by Mr. B. S. Trivedi and myself were described in a joint paper[7]. We are now examining further material, including the gypsum associated with the salt, and the 'oil shales' underlying the Marl near Warchha. We would

be grateful to geologists for any samples of saline deposits of disputed age from non-Indian sources, especially for authentic *in situ* material from the Iranian saline beds which Boeckh, Lees and Richardson have regarded as Cambrian, but which may be of the same age as the Kohat and Punjab salt.

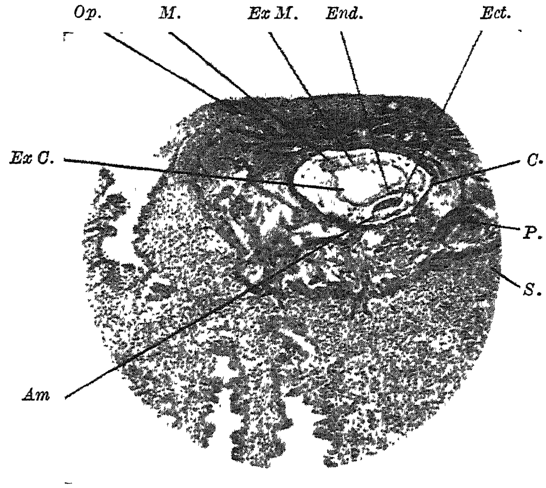
A Human Embryo, Nine to Ten Days Old

A normal previllous human ovum, estimated from both its histological study and the precise menstrual and coital history of the patient to be nine to ten days old, was found in the uterus removed from a young married woman. In its detailed structure it appears to show minor differences from the ovum *Wi*-8004 recently discovered by Rock and Hertig[1] and estimated by them to be 9·5 days old, although the comparison is based solely on a photomicrograph of one section of the latter ovum and the short preliminary report thereon so far published. These two ova represent the earliest specimens of fully implanted human ova yet discovered, and the present specimen shows several features of importance in the early organization of the human embryo.

Heuser and Streeter[2] stressed the precocious formation of the primitive mesoblast in the macaque monkey as compared with other mammals; the present specimen shows that in the human the formation of primitive mesoblast (*M*) is even more precocious. The germ disk has a diameter of 0·117 mm.; that in the 11·5-day Hertig-Rock ovum[3] is 0·138 mm. It consists of a single layer of columnar ectodermal cells (*Ect.*) and a single layer of cubical endodermal cells (*End.*); these two layers have been artificially separated in the process of preparation and no mesoblast penetrates between them. The thin exocoelomic (Heuser's) membrane (*Ex.M.*) is complete, in contrast with that in the 11·5-day Hertig-Rock ovum[3], and, together with the endodermal plate, it encloses the exocoelomic coelom (*Ex.C.*) or primitive yolk-sac. The definitive yolk-sac has not yet developed. The sudden transition of the cubical endodermal cells of the disk to the flattened cells of the exocoelomic membrane favours Heuser's view[4] that, whereas the endoderm is derived from



Section through equatorial region of embryo. (×45)

the formative cell mass, the membrane is formed from the mesoblast. Likewise the change from the columnar ectodermal cells to the flattened cells of the amnion (*Am.*) support the view of Ramsey[5] and Heuser and Streeter[2] that the amnion is mesoblastic in origin. The amnion is not yet complete and deficiencies in its roof are closed in by cytotrophoblast (*C*); here transition cells are found between cytotrophoblast and amnion. The plasmoditrophoblast (*P*) contains lacunæ in various stages of formation; maternal blood is found only in those lacunæ on the abembryonic (superficial) side of the ovum, elsewhere they contain leucocytes.

In the aborted ova described by Bryce and Teacher[6] and von Möllendorff[7], a zone of necrosis of the endometrium was observed surrounding the ova; consequently the belief was held for some time that implantation of the ovum was normally accomplished by necrosis of the maternal tissue. That this is not the case is indicated in the present specimen by the fact that normal stroma (*S*) abuts on the trophoblast. The operculum (*Op.*), indicating the site of entry of the ovum into the endometrium, consists of a mixture of fibrin and leucocytes permeated by plasmoditrophoblast. Ovulation was deduced to have occurred on the ninth day of the menstrual cycle of twenty-eight days; to this early time of ovulation is attributed the fact that the endometrium is as far advanced in the secretory phase on the twentieth day in the present specimen as that on the twenty-fourth or twenty-fifth day in a number of other specimens examined from women in whom ovulation probably occurred nearer the middle of the cycle.

A full account of this specimen is being published elsewhere.

Nature of Acid in Soft Water in Relation to the Growth of Brown Trout

IN 1937 I made a brief survey of some small lochs in Sutherland, in some of which the water was fairly acid (pH 4·5). I found, as Captain Sawyer[1] has done, that the pH of these waters could be changed very rapidly towards neutrality by shaking with air; and I concluded, like him, that the acidity was due mainly, if not entirely, to dissolved carbon dioxide.

An account of these observations was given to the British Association in 1937[2], and my deductions as to the cause of the acidity were criticized on chemical grounds. Later, further samples from these lochs were collected and were examined by the Government Chemist. He reported (*in literis*) that the water was acid, that the pH was not noticeably altered by aeration and that the acidity was due to a small quantity of a strong acid, of vegetable or peaty origin, in solution. That the pH of these samples could not be changed by aeration made me suspect that conditions in these lochs had changed and, by correspondence, I ascertained that this was so. The samples examined by the Government Chemist were taken after a period of heavy rain and were brown in colour, whereas mine were taken after some weeks of drought and were virtually colourless. It was hoped to continue these observations, but a change of programme and then the War have so far made it impracticable.

The conclusion is that Captain Sawyer has produced supporting evidence for the view that the acidity of the waters of these lochs may at times be due to carbon dioxide, but that the presence and importance of 'humic' acids can by no means be ignored.

Whether these factors have any direct bearing on the varying sizes attained by trout in different waters is open to considerable doubt. When Southern[3] produced the hypothesis that the growth of trout was directly related to the composition of the water in which they were living, he started a hare which many of us have followed for varying distances. I now believe that the solution of the problem is to be sought in the relation between the trout population and the food supply. That this line of attack has formerly been found to be unpromising[4,5] is due to over-emphasis of the latter factor and neglect of the former. It happens that, in soft or acid waters, spawning conditions for trout are often ideal, for the rocks are hard and the redds are consequently free from silt. Hence the percentage hatch is large[6] and the survival-rate continues to be high because the predatory fishes such as pike, perch and chub are absent from such waters. The pressure on the available food is accordingly great, and trout, with their extraordinary lability, respond to the conditions by a general decrease in growth.

In waters where the survival-rate is low, owing either to poor spawning ground or to the presence of predators, the trout grow big, whether the water is acid or alkaline[3].

It is hoped, when time permits, to develop this thesis in a paper in *Biological Reviews*.

Achilles and the Tortoise

PROF. F. G. DONNAN has submitted[1] a very interesting application of the exponential function. I think, however, that his first equation is not altogether accurate. I suggest that the following is rather more realistic.

If y and x are the distances of Achilles and the tortoise from a fixed datum, then

$$\frac{dy}{dt} = 10pe^{-\lambda t};$$

when $t = 0$, $y = 0$ and the constant of integration will be $10p/\lambda$ and

$$y = \frac{10p}{\lambda}(1 - e^{-\lambda t}).$$

$$\frac{dx}{dt} = pe^{-\lambda t};$$

when $t = 0$, $y = d$, their distance apart at the start.

So that the constant of integration is $\frac{p}{\lambda} + d$, and

$$x = d + \frac{p}{\lambda}(1 - e^{-\lambda t}).$$

If D is their distance apart after time t,

$$D = x - y = d - \frac{9p}{\lambda}(1 - e^{-\lambda t});$$

when $t = \infty$, $D = d - \frac{9p}{\lambda}$.

So D may be positive, negative or zero, which rather disproves Zeno's paradox.

G. SILYN ROBERTS.

Vincent House,
Pembridge Square,
London, W.2.

[1] NATURE, 153, 142 (1944).

THE statement of Group-Captain G. S. Roberts, that the first equation in my letter to NATURE to which he refers "is not altogether accurate", would appear to mean that it does not cover the general case of a tortoise with any possible start. It was made clear in my letter, however, that this equation applies only to the case of a tortoise with a *specified* start, namely, 10 units of distance. In this particular case I showed how it was possible, by a special adjustment of the ratio p/λ, to secure the result that Achilles would overtake this *particular* tortoise only in an infinite time. Given this particular (adjusted) value of p/λ, it follows that, for tortoises travelling according to the same law of speed, those with a start of less than 10 will be overtaken in a finite time, whereas those with a start of greater than 10 would not be overtaken by Achilles even in an infinite time.

It is, of course, a very simple matter to give a general algebraic statement valid for tortoises with all possible starts, but I did not consider that the interest of the problem warranted any further elaboration. It was, however, amusing to note that by a suitable adjustment of p/λ one could always make a 'cut' in the infinite set (of tortoises). This point has been well taken in an interesting letter which I have received from Mr. W. J. Chater of Northampton.

RESEARCH ITEMS

Promin Treatment of Leprosy

IN a recent paper (*Public Health Rep.*, 58, 1729; 1943) G. H. Paget, R. C. Pogge, F. A. Johansen, J. F. Dinan, B. M. Prejean and C. G. Eccles of the United States Marine Hospital (National Leprosarium), Carville, La., record their observations on the treatment of leprosy by promin, the sodium salt of *p.p.*diamino-diphenyl-sulphone-*n.n.*didœstrose sulphonate in a paper based on the study of forty-six cases. Their conclusions are as follow. (1) Promin is the sulphonamide drug which so far seems to possess to the greatest extent some chemotherapeutic properties against leprosy. (2) While no direct evidence of a specific bacteriostatic or bactericidal action against *M. lepræ* has been demonstrated, it has been observed that promin seems capable of inhibiting the progress of leprosy in a considerable number of cases. (3) Promin can be safely administered intravenously for prolonged periods provided the blood and urine are examined frequently. Toxic manifestations, of which hæmolysis is the most important, are relatively few and mild. (4) Further experimental and clinical studies on the treatment of leprosy with promin are required before more definite conclusions can be drawn.

Blennioid Fishes

EARL D. REID has published a review of the genera of blennioid fishes related to Ophioblennius (*J. Washington Acad. Sci.*, 33, No. 12; Dec. 1943). The work is based on examination of material in the collections of the United States National Museum from the tropical Atlantic and Pacific Oceans. The author recognizes five genera of these fishes, two of which, Leoblennius and Bleniella, are new. Keys are given to the genera and to the ten species referred to Ophioblennius, which is widely distributed in the tropical Atlantic, along the west coast of Africa and from the West Indies to Trinidad. In the Pacific it occurs from the coast of southern California to the Galapagos, Chile to the Marquesas, and the Hawaiian Islands. No species, so far, has been found away from the island or group of islands from which the type was recorded. Most of the species collected have been attracted to an electric light and captured in a dip net used from the ship's side while at anchor.

A Canadian Dinosaur

IN 1924 Dr. Gilmore described as *Troödon validus* a remarkable Canadian Cretaceous Dinosaur which combined a small but greatly thickened skull with a lightly built bipedal body. In 1939 the American Museum of Natural History secured a similar but much larger skull from a higher horizon in Montana. This animal has now been described by Barnum Brown and E. M. Schlackjer (*Bull. Amer. Mus. Nat. Hist.*, 82, Art. 5) as *Pachycephalosaurus grangeri*. This remarkable skull is two feet long—three times the size of Troödon—and the dome-like mass of bone over its cranial cavity is from six to nine inches in thickness, while the ventral parts, the palate, etc., are relatively slender. The greatly thickened parietal and frontal bones are known to be composed of finely cancellar bone with dense laminæ running out to the surface in Troödon, and are no doubt of similar structure in the new form. No suggestion has yet been made to account for this development. It can scarcely be protective, because the lightly built slender neck, body and limbs present so much larger a field for attack. A very similar thickening of the cranial roof is found in the Permian Tapinocephalid Deinocephalia, which are very far removed from the Dinosaurs. Indeed, the skull of Pachycephalosaurus mimics in a remarkable way that of these animals; it is of about the same size, has similar general proportions, and has very small teeth much like those of Mormosaurus; and in Tapinocephalids the parietal may be at least 6 in. thick. But the bodies of the members of the two groups are grotesquely unlike; the Deinocephalian body was a great barrel-like structure supported by four short, immensely massive legs, in contrast to the slender body and limbs of Troödon, and its habit of walking on the hind feet alone. It is, in fact, evident that the great thickening of the skull roof of Troödonts has no direct adaptive significance; it, and also that of Tapinocephalids, must be secondary effects resulting presumably from some endocrine unbalance persisting through many thousands of generations.

Hessian Fly Resistance in Wheat

W. B. NOBLE (*J. Agric. Res.*, 67, 27; 1943) shows that Dawson wheat contains two non-allelomorphic factors for resistance to Hessian fly. The progeny of Dawson × Poso and × Big Club, which are susceptible, have been examined. It was found that the two factors separately confer less resistance to Hessian fly attack than in a combined condition. By scientific breeding using this knowledge, recombinants containing both resistant factors have been produced.

Eye Responses of Drosophila Mutants

H. KALMUS (*J. Genetics*, 45, 206; 1943) has studied the optomotor response of different mutants in Drosophila and shows that wild type females with more ommatidia than males follow striped patterns better, whereas a reduction of ommatidia in the Bar series causes a reduction in the degree of response. Eyeless strains of *D. pseudo-obscura*, with about twelve facets, show no response. Homozygous vestigial winged flies react best of all stocks tested, while yellow, black and ebony mutants were similar to wild type. White-eyed flies, W/w, do not react to the striped pattern while homozygous brown-cinnabar flies and apricot flies and homozygous brown-vermilion flies react less than the wild type.

Ionization and Chromosome Breakage

D. G. Catchside and D. E. Lea (*J. Genetics*, 45, 186; 1943) have continued their work on the effect of X- and other rays upon chromosome breakage. They had previously shown that breakage resulted from a minimum of seventeen ionizations per break. They now compare the effect of ionizations from X-rays of different wave-length. The coefficients of chromatid breakage are highest with $\lambda = 4 \cdot 1$ A. and fall off through $\lambda = 1 \cdot 5$ A. to medium X-rays $\lambda = 0 \cdot 15$ A. to Al*K* radiation $\lambda = 8 \cdot 3$ A., where they are least. This is interpreted to mean that only the densely ionizing tails of the electron track are effective in chromosome breakage and that the tails have a higher efficiency only where they traverse the chromatid. When the radiation is performed respectively on pollen grain divisions and pollen tube divisions of Tradescantia, there is a difference in the coefficient of aberrations. The authors show that there is equal probability of survival of chromatid breaks in both

divisions, but interchange in the pollen tube is reduced by the cylindrical shape as compared with the spherical pollen grain nucleus.

New Plant Diseases

Lilian E. Hawker and B. Singh have described a disease of seedling lilies (*Trans. Brit. Mycol. Soc.*, 26, Pts. 3 and 4; Dec. 1943). This was caused by the fungus *Fusarium bulbigenum*, which has hitherto been reported as a pathogen of mature bulbs. The fungus can enter unwounded roots of seedlings and of *Lilium regale*, but cannot enter unwounded bulb scales. Infection from pure cultures of the pathogen produced the typical damping-off symptoms. Application of formalin dust to the seed boxes before sowing gave good control. C. J. Hickman and D. Ashworth record, in the same journal, the occurrence of Botrytis spp. on onion leaves. Three species of Botrytis are apparently involved. *B. squamosa*, recorded for the first time in Great Britain, was the predominant organism, and the others were the ubiquitous *B. cinerea* and another form as yet unidentified. Infection was limited to autumn and winter, and plants usually grew away healthy in spring and summer.

Archæan Rocks of South Harris

FOLLOWING up the pioneer work of Craig and Jehu on the geology of the Outer Hebrides, a detailed study of the Archæan gneisses of the Rodil district of South Harris has been made by C. F. Davidson (*Trans. Roy. Soc. Edin.*, **61**, 71; 1943). The oldest rocks are paragneisses representing a series of shallow-water sediments which included impure dolomitic types. These sediments were intruded by a complex of anorthosite and banded gabbro and norite accompanied by small ultrabasic intrusions. High-grade regional metamorphism followed, leading in general to the formation of eclogite and garnetiferous granulites or charnockites, together with calc-silicate rocks and garnet-kyanite-gneisses. Next came a phase of migmatitization due to the passage of a wave of volatiles through the rocks, whereby plagioclase was locally transformed to scapolite, pyroxene to hornblende and garnet to kelyphite. The final phase consisted of the formation of thick sheets and dykes of acid pegmatite. At a much later stage, possibly Caledonian, representatives of all these rocks were involved in a zone of intense shearing and dislocation, mainly along the east coast of the area. Within the shear zone ultracataclastic structures were developed, and on most of the gneisses close to the shear zone there was imprinted the epidote-saussurite facies characteristic of low-temperature alteration. The paper contains several new chemical analyses and is notable for a valuable discussion of the nature and mode of origin of eclogites and charnockites.

Scattering of Light by Small Particles

EXPERIMENTS to elucidate scattering in the sky and in optical instruments have been carried out by H. Zanstra, who has discussed his investigations on the scattering of light by small rock-salt crystals suspended in a saturated solution (*Mon. Not. Roy. Astro. Soc.*, **103**, 5; 1943). Faber produced artificial haloes in the laboratory by using suspensions of small crystals of various salts in their saturated solutions contained in a cell with parallel walls. Zanstra used Faber's method for producing scattering of a central image by small crystals of rock salt, and measured the intensity I of scattered light as a function of the distance r from the centre. A description of the experimental arrangement is given, and this is essentially that of Faber, except for the fact that monochromatic light is not used. For deflexions less than 20′, diffraction may account for the scattering in the given suspension, but for larger deflexions, between 20′ and 5°, the observations cannot be represented by the theoretical formula. In this case an empirical law connects the intensity with the distance r, the intensity varying as $1/r^{\alpha}$, with α equal to 2·28. This law is of the same type as that for long-range scattering about a stellar image, which was observed by Redman; the value of α in this case was 1·70. The main conclusions obtained suggest that the long-range scattering observed in celestial photographs arises from small ice crystals in the sky, such as are responsible for haloes, and it is believed that any kind of small particles in the atmosphere might produce a similar effect. Observations without rock salt show, however, that another part of the long-range scattering in astronomical observations may be due to the instrument, presumably by scattering of light by scratches, dust particles or edges of diaphragms.

Applied Electron Microscopy

IN a paper dealing with electron microscopy, J. H. L. Watson (*Canad. J. Research*, 21, 89; 1943) points out its advantage when a large depth of focus is desirable. A typical value is 10 μ as compared with 0·4–0·2 μ with optical microscopes. Many electron micrographs are reproduced, covering smokes, mine dusts, paper coatings, and botanical objects (including cutin, which is shown to assume a fibrous nature on older plants). It is suggested that the electron microscope may find application in the study of chromosomes, although it is emphasized that the use of the instrument in botany involves considerable time, experimentation, and skill in suitable preparation. Most of the magnifications shown are of the order of 1,000–1,500, but some (mine dusts) are of 16,100. No details of the electron microscope are given, but a special object holder is described.

Acids and Bases

THERE are two general theories of acidic and basic function. The first, generally known as the Lowry-Brönsted theory, is represented by the scheme $B + H^+ \rightleftharpoons BH^+$, where H^+ is the proton (an acid being defined as a source of protons) and B a base (for example, a weak acid anion, OH^-, an amine, etc.). In the second theory, proposed by G. N. Lewis (1938), a base is a species having a free electron pair which can enter the shell of another atom, and an acid a species which can accept such an electron pair: $A + :B = A:B$. This introduces no new bases but it insists that the proton is only one of many species which can accept an electron pair and so combine with a base, and such molecules as BCl_3 are regarded as acids. G. F. Smith (*J. Chem. Soc.*, 521; 1943) has pointed out that the hydrolysis of the chloroacetate ion, investigated by H. M. Dawson, E. R. Pycock and G. F. Smith (*ibid.*, 517), and of the bromoacetate ion, is subject to general basic catalysis, and the Brönsted catalysis relation holds for a series of basic catalysts, but not for certain cases. In the reactions no proton transfer can be involved, and this is in agreement only with Lewis's definition; the Lowry-Brönsted definition appears to be too narrow.

EDUCATIONAL RECONSTRUCTION IN INDIA

AT the thirty-first Indian Science Congress held in January, the presidential address delivered by Mr. John Sargent before the Section of Psychology and Educational Science deserves more than a passing notice, because of the practical and comprehensive manner in which he dealt with the enormous problem of educational reconstruction in the Indian Empire.

Mr. Sargent began at the very beginning by asserting that the cause of real education has not been helped by "the tendency of woolly-minded philosophers to assume that education with a big E is necessarily a good thing". The totalitarian countries, he points out, have given a timely reminder that education can be as powerful a means of corrupting as of improving the mentality of a nation. But it has always been an instinct of human nature to want to know about things, both to satisfy curiosity and to ensure the preservation of the race by enabling it to assert control over its environment. No free nation which has once had a system of education would submit to be deprived of it. The Indians, of all people, need it, because they now range themselves among the United Nations, pledged to the ideal of democracy, and "democracy, like education, is not necessarily a good thing. It is the sort of democracy that matters." If a little learning in an individual is a dangerous thing, a little learning in a nation is not less dangerous. An India, "85 per cent of whose population are illiterate and liable, as we have seen in recent years, to be stampeded by political or religious excitement, however irrational, constitutes a field for mischief-makers". In other words, India owes it to her allies the world over to overhaul her educational provision thoroughly. "Whatever may satisfy government or big business or all the other vested interests whose vision is oblique or retrospective, the logic of any post-war settlement will demand a drastic change in the present state of things".

Upon such a foundation of principle, Mr. Sargent proceeded to raise a superstructure of Indian education as, in his belief, it ought to be, and in course of time can be. His minimum programme is comprised under a dozen headings, familiar to an English reader. They include compulsory and free schools from five or six to fourteen years of age, a reasonable supply of nursery schools, secondary schools of different types, university education for picked students, technical, commercial and art education, adult education of all kinds and standards, teachers' training institutions, special schools, recreational facilities, employment bureaux, and an efficient system of administration. Judged by the system in Great Britain, this is not an extravagant programme. Mr. Sargent then turned to consider how far the Indian system, as it exists to-day, falls short, and whether it is practicable to build upon it a national system on the lines suggested.

Mr. Sargent takes each item of his minimum programme, and deals with it faithfully. Less than one out of every four children stay long enough at school to attain "permanent literacy", so that the money spent on the others (nearly 80 per cent) may be regarded as wasted. In India, as elsewhere, only a tiny part of the vast army of teachers required enter the profession because they feel called to it; the rest must be attracted by decent prospects of a living, and there India has an immense problem. Of buildings and equipment, at any rate in the lower stages, "the less said the better". There is an obvious need for a youth movement on an All-India scale; and so on through a rather depressing catalogue, which, however, does not prevent Mr. Sargent from courageously facing the problems of finance. There is, he says, reason to hope that "as education spreads among the rural population it may lead to the abandoning of those superstitions and prejudices which for centuries have hung like millstones round the neck of the Indian peasant". A competent observer has estimated that with the removal of these, the standard of living among agriculturists might be raised by as much as 100 per cent. "Given the will and given the funds," concludes Mr. Sargent, "it would in my opinion take at least 35 to 40 years to establish the sort of system outlined in this paper."

The outlook for India, as thus presented, seems by no means depressing. Vast India may be likened to a lot of little Englands put together, and in the England of a century ago illiteracy was nearly as common as it now is in India, and most forms of education did not exist or were struggling for life.

T. RAYMONT.

BASICITIES OF THE AMINOQUINOLINES: COMPARISON WITH THE AMINOACRIDINES AND AMINOPYRIDINES

By DR. ADRIEN ALBERT
University of Sydney
AND
REGINALD GOLDACRE
Council for Scientific and Industrial Research, Melbourne

IN view of the use that has been made, in recent years, of the aminoquinolines as intermediates in the evolution of new drugs, it is surprising that no measurements of their strengths as bases have been published. Briefly, the history of these drugs is that the antimalarial, pamaquin, introduced in 1926 under the trade-name of 'Plasmoquine', was the first chemotherapeutic substance derived from an aminoquinoline; in 1937 three more aminoquinoline drugs appeared, namely, the wound-antiseptic 'Surfen' and the trypanocides 'Surfen-C' and Bayer 7602, the latter being intended as a specific for *T. cruzi* infections in South America. Later, 'Acaprin', another aminoquinoline drug, became established as a specific for certain piroplasmoses. In Moscow in 1937, Maghidson and Rubstov[1] discovered some malarial schizonticides in this series[2], but the development of new aminoquinoline drugs has taken place mainly in Germany: Iensch[3], even in 1937, was able to review the structure and activity of some hundreds of these compounds, and work of this kind has apparently gone on steadily[4].

The dissociation constants of the seven isomeric aminoquinolines have now been determined and are compared in Table 1 with the dissociation constants of the corresponding aminoacridines and aminopyridines. Because the acridine nucleus is numbered differently from the others, the table has been arranged with analogously substituted compounds opposite one another.

The favourable solubilities of the aminoquinolines has facilitated potentiometric titration of these substances in water (glass electrode; 0·001 gm. mol. in 60 mils). For comparison we reprint our results for the aminoacridines in 67 per cent methanol, since the sparing solubility of these compounds stands in the way of their accurate determination in water. As Mizutani[5] has indicated, pK values obtained in methanol of this strength are 0·3–0·9 unit too low, and hence a better approximation to the true values may be had by adding 0·5 unit to the aminoacridine results quoted here than by relying on figures obtained in water under conditions of non-equilibrium[6]. The three aminopyridines are freely soluble in water and we have taken the basicity figures (conductimetric) from the literature.

the analogously constituted 2-aminoacridine indicates that it, too, is rightly placed in class iii.

What is the cause of these exaltations in basicity? In 1941 we suggested tentatively that in the acridine series such exaltations are connected with the fact that the isomerides exhibiting this property can be depicted tautomerically as imines; for example, formula I for 2-aminoacridine. In the quinoline series, only the 2-, 4-, 5- and 7-isomerides can be written in analogous fashion, as has been done in formulæ II, III, IV and V respectively.

A mechanism by which this possibility of tautomerism affects the basicities of the aminoacridines has recently been worked out[6] and is capable of expansion to include the aminoquinolines and aminopyridines.

TABLE 1. FIRST DISSOCIATION CONSTANTS OF SIMPLE HETEROCYCLIC AMINES.
(Expressed as pK_a, the negative logarithm of the acidity constant.)

Quinoline series	pK_a in water at 20° C. *	Criterion of purity	Acridine analogues **	pK_a in 67% methanol; 20° C.	Pyridine analogues	pK_a in water
Quinoline	4·94	b.p. 132°/40 mm.	Acridine	4·54	Pyridine	5·21†
8-Aminoquinoline	3·93	m.p. 65°	1-Aminoacridine	3·68	(no analogue)	
7-Aminoquinoline	6·65	m.p 94°	2-Aminoacridine	7 60	(no analogue)	
6-Aminoquinoline	5·62	m.p. 117°	3-Aminoacridine	5·30	(no analogue)	
5-Aminoquinoline	5·51	m.p. 110°	4-Aminoacridine	5·74	(no analogue)	
4-Aminoquinoline	8·46	m.p. 69–70°	5-Aminoacridine	9 34	4-Aminopyridine	9·1 ††
3-Aminoquinoline	4 95	m.p. 94°	(no analogue)		3-Aminopyridine	6·6 ††
2-Aminoquinoline	7·34	m.p. 131°	(no analogue)		2-Aminopyridine	7·2 ††
					ditto	6·86*

* Newly determined by potentiometric titration, glass electrode, 20° C.
** From Albert, Rubbo and Goldacre, NATURE, **147**, 332 (1941); glass electrode.
† From Britton and Williams, *J. Chem. Soc.*, 796 (1935); glass electrode, 18° C.
†† From Tropsch, *Monatsh.*, **35**, 777 (1914); conductimetry, 25° C.

Discussion of results. As with the aminoacridines, the values for the aminoquinolines fall into three groups. Class i, where the pK value is approximately 1 unit *lower* than the value for quinoline, is represented only by 8-aminoquinoline. This tenfold weakening of basicity is evidence of an *ortho* effect as in the analogous 1-aminoacridine[7]. We have not

yet established in either case whether this *ortho* effect is due to hydrogen-bonding or is simply a steric hindrance to the approach of the hydronium ion. Class ii, where the pK is not more than 1 unit *higher* than quinoline, contains the 3-, 5- and 6-isomerides, which are hence considered as the normal amino derivatives of quinoline. Class iii consists of derivatives which are considerably more basic than quinoline, notably 2- and 4-aminoquinolines, the latter being more than three thousand times stronger a base than quinoline. Although 7-aminoquinoline is only fifty times as strong as quinoline, comparison with

Briefly, the ion of 4-aminoquinoline may be written as III*a*, which is derived from the normal form of the base, and also as III*b*, which is derived from the tautomeric imine III. The two forms of the *base* differ from one another in the position assigned to an atom of hydrogen, and hence, regardless of whether they can exist apart from one another, they cannot (by definition) be resonant with one another. On the other hand, the *ions* theoretically derived from them differ from one another only in the distribution of electrons and hence, provided that not too much of the unionized base's *nuclear* resonance is destroyed in the process (for example, by converting a benzene ring into an *ortho*quinonoid structure), the ions will exhibit a higher degree of resonance than the unionized base. The larger this 'extra ionic resonance energy' is, the greater will be the basicity of the amine because of the increasing tendency to pass over into the more stable ion. This serves to explain the exaltation of 4-aminoquinoline, which can readily change into the ion, which is a resonance hybrid of both III*a* and III*b*. As is usual where a high degree of ionic resonance is present, the second pK is greatly reduced. The exaltation in the analogously constituted 5-aminoacridine and 4-aminopyridine is of the same order.

The ion of 2-aminoquinoline can similarly be considered as a resonance hybrid derived from the normal amine and the tautomeric imine II, which is essentially an amidine. This base is weaker than 4-aminoquinoline because the resonance depends on an *ortho*quinonoid contribution; likewise it is very much weaker than the aliphatic amidines, where the base-strengthening resonance is facilitated by sym-

TABLE 2. 3-AMINOQUINOLINE.

Percentage neutralized	7	13	20	27	33	40	47	53	60	67	73	80	87	93
pK_a value	5·04	5·05	4·96	4·97	4·96	4·94	4·95	4·93	4·92	4·94	4·92	4·94	4·96	5·09

metry and the absence of competition with nuclear resonance[8,9]. In 2-aminopyridine, where all Kekulé-type resonance has been lost in one contributing form, the exaltation is vanishingly small. This diminution in resonance by loss of a benzene ring is seen again in the diminished exaltation of 7-aminoquinoline V, as compared with its analogue, 2-aminoacridine. Finally, no extra ionic resonance is observed in 5-aminoquinoline (corresponding to practically none in 4-aminoacridine). This may well be because an ion derived from the imine IV, in addition to being *ortho*quinonoid (a structure that is relatively unstable and does not readily take part in ionic resonance[10]), must also lose both the Kekulé-type rings of quinoline.

An interesting by-path in these investigations has been the examination of our titration figures for 3-aminoquinoline in order to confirm the existence of the semi-hydrochloride that Mills and Watson[11] postulated on the grounds of colorimetric and cryoscopic anomalies. However, the constancy of the *p*K values obtained on adding one equivalent of hydrochloric acid to the base (Table 2) gives no indication of its formation.

While these simple aminoquinolines do not themselves possess marked chemotherapeutic properties, the main types of basicity discussed here will persist in their active derivatives. For example, pamaquin, a derivative of 8-aminoquinoline and the only aminoquinoline drug yet investigated, has a pK_a of 3·55[12]; similarly, in the acridine series the exaltation seen in 5-aminoacridine persists in its derivatives 'Rivanol' and 'Atebrin'.

Because bases with *p*K values below 6 are less than 10 per cent ionized at *p*H 7, while those with values above 8 are practically completely ionized, a biologically important difference exists between drugs based on different aminoquinolines, and this should not be overlooked in interpreting the action of known drugs and in devising new ones.

EARTH-FAULT RELAY EQUIPMENT

A PAPER entitled "A Modern Earth-Fault Relay Equipment for use on Systems Protected by Petersen Coils" was read in London recently by L. B. S. Golds and C. L. Lipman before the Institution of Electrical Engineers, and in it the authors dealt with the automatic isolation or indication of earth-faults on such systems. After discussing the operating principle of this type of protection, describing the working of a wattmeter-type relay, and enumerating the electrical constants of the type of system to which the protection is applied, the paper describes the application of the relay to an actual 66-kV. system.

The currents in the feeders are analysed and the problem of accurate current summation is discussed in detail. A comparison is made between current summation by means of a summation transformer and by direct paralleling. Results are given of laboratory tests on current-transformers at currents approximating to the system capacitance currents. Further test figures are given showing the effect of load current in addition to capacitance currents. The design of the relay element, its constructional features and operating characteristics are described.

From experience gained on tests with artificial faults and under actual system earth-fault conditions, the relays were found to be quite reliable in operation, providing the equipment was connected correctly and the current-transformers were sufficiently accurate. When commissioning the gear, an artificial fault is valuable in proving the reliability of the equipment. By observing the operation of the relays at each sub-station with faults at selected points, the complete scheme can be put into operation with a minimum of testing. Preliminary tests are carried out by single- and three-phase injection to ensure that the transformers are balanced and that they comply with the specification.

These relays are being used in conjunction with phase-fault relays to switch-out one faulty line in the event of a double earth-fault, leaving the original fault on the system. The difficulty of extreme sensitivity has been overcome by the use of a resistance in series with the coil, which serves the double purpose of limiting the asymmetric current under healthy conditions and increasing the active component under fault conditions; this has the advantage of making the relay more robust.

FORTHCOMING EVENTS

Monday, April 17

INSTITUTION OF ELECTRICAL ENGINEERS (CAMBRIDGE AND DISTRICT WIRELESS GROUP) (at the Technical School, Cambridge), at 5.30 p.m.—Mr. B. J. Edwards: "A Survey of the Problems of Post-War Television".

Tuesday, April 18

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Mr. Hans E. Adler: "Life in Soviet Turkestan".

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 4.30 p.m.—Mr. H. Thomas: "Co-operative Cataloguing"; Colonel Luxmoore Newcombe: "The Library of Congress Depository Catalogue and Bibliographical Service at the National Central Library".

EUGENICS SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. D. Caradog Jones: "The Standard of Living".

ILLUMINATING ENGINEERING SOCIETY (joint meeting with the SCIENCE MASTERS' ASSOCIATION) (in the Large Physics Lecture Theatre, Imperial College of Science, Imperial Institute Road, South Kensington, London, S.W.7), at 5 p.m.—Following a short introductory Address a series of Experiments illustrating the Production and Nature of Light, Photometry, the Fundamental Principles of Illuminating Engineering, and the Advantages of Good Lighting will be demonstrated and discussed.

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5 30 p.m.—Discussion on "Metals and their Finishes in Radio Construction" (to be opened by Dr. G. L. Sutherland).

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London, S.W.7), at 6 p.m.—Mr. Y. A. C. Yule: "Unsharp Masks, a New Method of Increasing Definition in Prints".

Wednesday, April 19

SOCIETY OF CHEMICAL INDUSTRY (joint meeting of the MICROBIOLOGICAL PANEL OF THE FOOD GROUP, THE AGRICULTURE GROUP AND THE ASSOCIATION OF APPLIED BIOLOGISTS) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 11 a.m.—Papers on "Soil Sterilization". (Dr. W. F. Bewley: "Some Problems in Soil Sterilization"; Mr. W. J. C. Lawrence: "Soil Sterilization and Seedling Growth"; Mr. A. H. Dodd: "Considerations in Chemical Soil Sterilization"; Mr. H. Lees and Dr. J. H. Quastel, F.R.S.: "A New Technique for the Study of Soil Sterilization" (with Demonstration); Mr. H. Lees and Dr. J. H. Quastel, F.R.S.: "Effects of Chlorate Administration on Soil Nitrification").

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. A. C. Cameron: "Education To-day and To-morrow", 8: "School Broadcasting".

GEOLOGICAL SOCIETY OF LONDON (joint meeting with the INSTITUTION OF WATER ENGINEERS) (at Burlington House, Piccadilly, London, W.1), at 2 p.m.—Discussion on "Sources of Water in relation to Town and Country Planning".

INSTITUTION OF NAVAL ARCHITECTS (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 2.30 p.m.—Address by the President (Admiral of the Fleet the Rt. Hon. Lord Chatfield, G.C.B., O.M.).

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 2.30 p.m.—Discussion on "The Limitations and Uses of the Comparative Method in Medicine", 4: "Neurology and Psychiatry" (to be opened by Dr. Dorothy Russell, Dr. J. R. M. Innes, Dr. W. S. Gordon, Dr. W. H. Andrews and Prof. Samson Wright).

Thursday, April 20

MANCHESTER CHAMBER OF COMMERCE (at Houldsworth Hall, Manchester), at 11.30 a.m.—Sir Edward V. Appleton, K.C.B., F.R.S.: "Fundamental Research—its Practical Importance".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. W. H. Mills, F.R.S.: "Old and New Views on Some Chemical Problems" (Presidential Address).

INSTITUTE OF THE PLASTICS INDUSTRY (LONDON AND DISTRICT SECTION) (at the Waldorf Hotel, Aldwych, London, W.C.2), at 6.30 p.m.—Mr. D. N. Davies: "Polyvinylchloride".

ELECTRICAL ASSOCIATION FOR WOMEN (joint meeting with the WOMEN'S ENGINEERING SOCIETY) (at 20 Lower Regent Street, London, S.W.1), at 7 p.m.—Conference on "Women in the Building Industry".

Friday, April 21

INSTITUTION OF ELECTRICAL ENGINEERS (MEASUREMENTS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. L. Jacob: "A New Type of Electron-Optical Voltmeter".

INSTITUTE OF PHYSICS (LONDON AND HOME COUNTIES' BRANCH) (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Display of Scientific Films by Mr. N. L. Harris and Mr. M. Michaelis.

Saturday, April 22

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 2.30 p.m.—Dr. J. Blair Hartley: "The Future of Radiology in Obstetrics".

INSTITUTE OF PHYSICS (INDUSTRIAL RADIOLOGY GROUP) (at the Royal Institution, 21 Albemarle Street, Piccadilly, London, W.1), at 2.30 p.m.—Mr. W. H. Glaisher, Dr. W. Betteridge and Mr. R. Eborall: "The Mottling of Aluminium Alloy Radiographs".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEAD OF THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Principal, Harris Institute, Preston (April 20).

LECTURER IN INORGANIC OR PHYSICAL CHEMISTRY to Higher National Certificate or Degree standard—The Principal, Royal Technical College, Salford 5, Lancs. (April 21).

GRADUATE LECTURER IN MECHANICAL ENGINEERING, a GRADUATE LECTURER IN ELECTRICAL ENGINEERING (preferably with experience in RADIO), and a GRADUATE LECTURER IN CHEMISTRY (with subsidiary MATHEMATICS, PHYSICS or BIOLOGY), at the Southend Municipal College—The Chief Education Officer, Education Office, Warrior Square, Southend-on-Sea (April 22).

SENIOR SPEECH THERAPIST—The Director of Education, Education Offices, Nelson Square, Bolton, Lancs. (April 22).

ASSISTANT MASTER FOR TECHNICAL SUBJECTS in the Municipal Technical College—The Secretary, Education Office, Town Hall, Widnes (April 22).

CHAIRS OF MATHEMATICS, PHILOSOPHY and PHYSICS, tenable at Bedford College for Women—The Academic Registrar, University of London, Richmond College, Richmond, Surrey (April 24).

INSTRUCTOR IN BEEKEEPING (temporary) on the Agricultural Instruction Staff of the Somerset County Council—The Clerk to the Somerset County Council, County Hall, Taunton (April 24).

COMBUSTION ENGINEER to undertake Shift Duties at a large Power Station in London—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2074XA) (April 24).

ASSISTANT ENGINEER by the Great Yarmouth Electricity Undertaking—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.799XA) (April 24).

ASSISTANT MAINS ENGINEER (location, Essex)—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.800XA) (April 24).

TEACHER (man) OF MATHEMATICS (with subsidiary SCIENCE) at the Cambridgeshire Technical School—The Education Secretary, Cambridgeshire Education Committee, Cambridge (April 24).

ASSISTANT LECTURER IN CHEMISTRY (with special qualifications in PHYSICAL CHEMISTRY)—The Registrar, The University, Manchester 13 (April 25).

LECTURER IN CHEMISTRY to teach PHYSICAL and INORGANIC CHEMISTRY up to Honours B.Sc. standard, at the Cardiff Technical College—The Director of Education, Education Offices, Cardiff (May 1).

SUPERINTENDENT to take charge of modern factory in South-East Essex producing Soap Products, Glycerine and Fatty Acids—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2091XA) (May 1).

ASSISTANT MASTER to teach MATHEMATICS at any stage up to University Scholarship work at the City of London School—The Town Clerk, 55-61 Moorgate, London, E.C.2 (May 1).

DRUMMOND PROFESSORSHIP OF POLITICAL ECONOMY—The Registrar, University Registry, Oxford (May 13).

ENGINEERING INSPECTOR OF MINES (temporary) in a Government Department—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2088A) (May 17).

W. H. COLLINS PROFESSORSHIP OF HUMAN AND COMPARATIVE PATHOLOGY—The Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2 (July 31).

SENIOR LECTURESHIP IN THE DEPARTMENT OF METALLURGY of the University of the Witwatersrand—Dr. W. Cullen, 4 Broad Street Place, London, E.C.2 (July 31).

GRADUATE LECTURER IN MECHANICAL ENGINEERING at the Municipal College, Southend-on-Sea—The Chief Education Officer, Education Office, Warrior Square, Southend-on-Sea.

JUNIOR CHEMIST for an Iron Ore Mine in Sierra Leone—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 406).

LECTURER FOR BIOLOGY AND HYGIENE—The Principal, St. Katharine's College, Tottenham, at Cary Park, Babbacombe, Torquay.

UNIVERSITY DEVELOPMENT IN GREAT BRITAIN

THERE are three main reasons for the attention which is now being concentrated in Great Britain on the development of the universities. In the first place, the quickened interest in education generally, which has led to the introduction of the Education Bill and the widespread approval of the White Paper on Education, induce the consideration of the universities as a part of that system, and their ability to meet the demands of the post-war society. That interest has been strongly reinforced by the growing concern with social problems and the realization of the relation between education and the society whose needs schools, universities and technical colleges have to meet, as the proceedings of the annual conferences of the National Union of Students or the most casual survey of the immense literature on reconstruction will attest. Still further, and more urgently, attention has been focused on the universities from the point of view of their equipment to meet the country's needs in regard to research and of the training of the greatly increased number of research workers which will be required after the War.

On all these counts there is now general agreement that the financial resources of the universities of Great Britain must be much increased, and that in the main this increase must come from Government grants. The urgency of increasing the provision for research at the universities and for training research workers has been stressed in recent reports and discussions on demobilization, while the statement in the report of the Parliamentary and Scientific Committee on "Scientific Research and the Universities in Post-War Britain" could scarcely be bettered. This aspect is receiving the particular attention of the special committee under Lord Hankey, while the extent of the interest in the broad question of university education generally is to be seen in the activities of the British Association Committee on Post-War University Education, which has already issued several reports, and in the prominence given to the question in recent reports on industrial and scientific research, notably that from the London Chamber of Commerce.

A report entitled "University Developments" has now been issued by the Association of University Teachers*, following its adoption by the Council of the Association on December 16, 1943. The British Association Committee has issued a further note reviewing its earlier reports and suggesting a universities council to plan and guide the developments suggested. The same question is still further examined by Sir Ernest Simon in a pamphlet, "The Development of the Universities"†, while Prof. G. C. Field has contributed an important article, "Problems of the Modern Universities", to the April issue of *Agenda*.

Several of these reports and papers admittedly owe

* Association of University Teachers. Report on University Developments. Pp. 16. (Bristol: J. W. Arrowsmith, Ltd., 1944.) 1*s*.

† The Development of the Universities. By Sir Ernest Simon. Pp. 20. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1944.) 1*s*. net.

something to one or other of three recent books on the universities, notably to Bruce Truscott's "Red-brick University". F. R. Leavis's "Education and the University" is concerned more specifically with the organization of a School of English as a real humane focus capable of discharging the function of a university in the matter of liberal education. Brian Simon's "A Student's View of the Universities", admittedly a *cri au cœur* and revealing the trend of thought among student members, adds little to the discussion that could not be found in H. C. G. Herklot's "The New Universities" in 1928. The specific problems of the Scottish universities have since been discussed from the student's point of view by J. H. Burns and D. Sutherland Graeme in a still more recent book, "Scottish University".

The questions discussed in this mass of literature vary widely in importance and urgency. They range from details of internal discipline, amenities, organization, scholarships and examinations, to the ultimate functions of the universities and their relations to one another and to the State. In so far as they are raised by the immediate proposals for university expansion, they may be placed, according to urgency or timing, in three main, though overlapping, groups : those of function, such as the relations between the universities and society, their regional responsibilities, or the balance between research and teaching ; questions of organization, such as the size and distribution of faculties and research schools, the administration and distribution of grants, and the external relations of universities with one another and with the State ; and finally, internal problems such as the status and salaries of academic staff, scholarships and fellowships, the provision of medical and social facilities for students, halls of residence and the like.

There are first the fundamental questions as to the functions of the universities and their place in the society of to-day. Unless we have clear ideas as to the functions the universities are to serve, we cannot assign them their right place, either in the educational system, in our organization for research or in society as a whole. Without such ideas their interrelations and organization cannot be profitably considered or the available national resources wisely apportioned. The necessity for clarifying our ideas on this question is well emphasized by such suggestions as the creation of a British university for the printing and allied crafts which was recently seriously advanced in a reputable technical periodical.

While such a challenge to fundamental thinking is urgent and cannot be ignored, this group of questions is not of first importance at the present time, and is rather of the long-term type. Creative thought cannot be forced, and all we can expect to achieve in the near future is such rebuilding of our educational framework as is necessary to stimulate the creative forces and to encourage experiments in accordance with the needs of our age of transition. What should be kept in mind is that the changes introduced to meet the immediate and urgent needs should not be such as to impede more far-reaching changes or developments which further inquiry and investigation may indicate as desirable. Our immediate measures should be such as to provide the largest possible amount of evidence as to the direction and magnitude of any further changes. The loosening of structure, to which the universities like all other social institutions have been subjected during the War, should assist the promotion of such experiments, and enforce the lesson that all social institutions must be regarded as dynamic rather than static if they are to remain in vital touch with the society they profess to serve.

The most urgent problems involved in the expansion of the universities to meet the immediate post-war needs in regard to the training and re-training of demobilized men and women, and the provision of the increased numbers of research workers and other scientific workers and technicians and of the facilities for fundamental research, are those of the second group. University expansion could well be handled so as to provide the experience and guidance for ultimate decisions as to appropriate size and numbers of our universities, their relation to the technical colleges, the balance between research and teaching, the content and scope of curricula, the relations between the State and the universities, the nature of internal organization, and the mechanism of endowment and entry. On many of these questions it is doubtful if we have sufficient data for final decision, and there is an admirable note of caution sounded by the more constructive critics, as in Prof. Field's article and in Dr. Löwe's "The Universities in Transition", in regard to such matters as the residential system, the lecture or the tutorial system, on which there has been a tendency in some quarters for rather hasty generalization and action which might prove too drastic or even unnecessary.

These questions are approached by the Association of University Teachers on four unexceptional principles. First, an essential function of the universities is the pursuit of knowledge untrammelled by any private or corporate interest. This is part of that wider freedom of expression of opinion on all matters of public concern which university teachers claim as their right as citizens. Their function of teaching is equally essential, and the universities in their instruction must embrace training in methods of thought and research as well as factual information. Third, the universities are schools of communal living in which the development of students as individuals is equally important with their development as social beings. Finally, the universities are part of society and bear a direct responsibility to it. They must therefore study the application of organized knowledge to practical problems, and train men and women for particular tasks.

Leaving for the present the observations of this report on questions falling in the third group, such as entry to the university, including both the entrance examination and the degree courses, we may note that the Association reckons on a 50 per cent increase of the student population of Great Britain—which would still leave the ratio of students to population in England and Wales considerably lower than that in some countries, according to 1934 figures—and that it emphasizes the urgent social need for a larger flow of trained and educated citizens. Its observations on

the structure of the universities and on co-operation between the universities, however, open in further detail a subject on which the recent reports of the London Chamber of Commerce and the Parliamentary and Scientific Committee have touched from one particular point of view, and to which Sir Ernest Simon devotes the major part of his pamphlet. The Association approaches this question with the object of determining what changes should accompany the expansion of the universities, which inevitably must mean closer co-operation between the universities and the outside world. Only by the growth of responsible self-government, the Association believes, can the universities meet both the opportunities and the dangers of the future, and whatever changes are made, liberty of thought and self-expression is an essential condition of progress.

First, as regards internal organization, the Association is much less forthright than Prof. Field, who sees no valid reason for the continuance of the council of a university and would go so far as to eliminate the local grant, except for specific purposes. He does not fail to recognize that universities may have special duties towards their own regions but, like the Association, he insists that much of the work of the universities has no specific regional bearing. The Association of University Teachers, however, considers that the present representative character of university courts and councils is appropriate to the present situation and stage of development of the regional universities, and contents itself with a plea for adequate representation of the academic staff on the council.

It might perhaps be too much to expect the Association's report to be as outspoken in such matters as Bruce Truscott in "Redbrick University", or as Prof. Field, but it is clear that the question merits much more fundamental consideration. In principle, the universities should undoubtedly be self-governing communities of teachers and research workers, and as Prof. Field points out, the present system cannot be rationally defended except on the grounds that it is already in existence. Probably the only reasonable line of advance is that which he suggests, and which is in accordance with the trend of the recommendations of the Association: the gradual extension of academic representation on the councils until the latter become predominantly academic bodies, and the recognition of the academic bodies as possessing the decisive voice in the elections to chairs.

The external aspects of university organization—their relations with the State—are, however, even more important at the present time. The report of the Association here frankly recognizes the need for co-ordination or planning of university development. First, it suggests that the number and size of universities require consideration. In size a university should range from 2,000 to 5,000 students, providing residential accommodation is available for a large number of students; and the first aim of a national university policy in Great Britain should be to build up the smaller universities to this size and to transform some of the university colleges into true independent universities.

Neither the University Grants Committee nor the Committee of Vice-Chancellors and Principals is regarded as competent to deal with all the problems arising out of future university development, which demands a closer association of the universities than hitherto; and it is proposed, therefore, that an academic council be set up by the universities, large and representative enough to be competent to discuss the work of the universities from all sides, and empowered to send recommendations to the University Grants Committee. Such a method is considered a surer and more efficient method of promoting the well-being of the universities than the plan of attaching their policy to a particular Department or Minister of State. The universities touch the life of the community at so many points that if they are, as a whole, to have direct access to the Government, the most appropriate channel might be the Privy Council.

Much the same point is made in the report of the British Association Committee, which suggests that the University Grants Committee might function as a committee of the Privy Council instead of, as at present, directly under the Treasury. The principal feature of this report, however, is its support for the proposal for a universities' advisory council previously advanced by the Parliamentary and Scientific Committee, and also for the view that the council should be entirely free from Government control. Such an advisory council should include the vice-chancellors of the universities and the principals of the university colleges, teachers of various grades in the universities and persons of distinction, for example, from industry, agriculture, medicine, education and government services. The council would require a full-time paid chairman and other staff, partly to assist in statistical inquiries. It would appoint committees to deal with various aspects of university life and with particular departments of university teaching and research, to which specially qualified persons could be co-opted. With such assistance, the council would be able to formulate a national policy of education and research, consider and report on all the national and international aspects of British universities and advise the universities.

A further function of the universities' advisory council might be to organize an annual conference of universities, which any teacher or research worker or administrative officer of any British university could attend, and at which various aspects of university policy could be discussed. A most important function of such a council would be to make representations on the financial needs of the universities to the University Grants Committee, or to any other appropriate body which might be appointed to advise the Government in that field, or a part thereof, as, for example, research. Such a council would also form the appropriate link with universities in other countries and such bodies as the International Education Organization, at first perhaps through the United Nations Relief and Rehabilitation Administration, in dealing with the development, including the reconstruction and rehabilitation, of post-war universities.

The statement in this report owes its inception to a statement by Sir Ernest Simon, who has further detailed his views in his more recent pamphlet, which

sets forth convincingly the limitations of existing machinery. He argues that, as a result of the absence of any national body responsible for studying the work of the universities as a whole, and considering how far all essential fields of thought are covered, there is sometimes redundancy, and sometimes a dearth in the facilities for teaching and research in important subjects, apart from the frequent delay of many years between important new developments and the time when their effective study in the universities is commenced. As examples, Sir Ernest points to aeronautical engineering; no university engineering school in Great Britain is equipped for aeronautical research on a substantial scale. Again, not one of the eight schools of mining is on a really adequate scale: between them they turn out twenty graduates annually, while six university forestry departments yield between them not more than twenty-five graduates a year.

Such disparities seem to make it of first importance that some suitable machinery should be established to study these questions and to ensure that any further increases in the university grant shall be wisely distributed in the best interests of the nation as a whole. Sir Ernest Simon, it is true, pays a warm tribute to the success of the University Grants Committee in distributing a large Government grant without any interference with the essential freedoms of the universities. None the less, he gives a convincing demonstration of the limitations of the present Committee, as well as of the Vice-Chancellors' and Principals' Committee and the Universities' Bureau, in regard to staff and functions and machinery. Substantially stronger staffs are essential for all three bodies if they are to increase their responsibilities to cover the needs which are now indicated.

Sir Ernest advances the suggestion that the University Grants Committee should co-ordinate the work of the Department of Scientific and Industrial Research, the Medical Research Council, the Agricultural Research Council, and the Royal Society, and itself allocate substantially larger grants to research in the various universities in whichever may be decided to be the best method. For example, he suggests that the University Grants Committee should appoint an Engineering Advisory Committee, and instances the question whether a strong school of chemical engineering should be established in Manchester as one which, like the development of chemical engineering abroad, is eminently suitable for consideration by a national body. The University of Manchester is at present studying the best lines of development and co-ordination of its two Schools of Engineering, one at the University and one at the College of Technology, each with two professors. A national advisory committee might well suggest the establishment of a chair of chemical engineering with a strong research department and recommend an appropriate grant for this purpose from the University Grants Committee.

Similar advisory committees would be necessary to deal with the principal subjects, especially with those which involve a substantial amount of research and of plant for research purposes. Other committees might deal with such problems as student life and welfare, halls of residence, the regional development of the civic universities, and the whole question of the relations with foreign, Dominion and Colonial universities. Such committees, with whole-time paid secretaries, of wide experience as well as of sound judgment, should provide an effective means of associating younger persons with the work of the University Grants Committee and thus meet a criticism which has been advanced against it.

Strengthened in such ways as these, Sir Ernest Simon proposes that the Universities Grants Committee should be competent to allocate capital grants to individual universities for specific purposes; to allocate annual grants to individual universities for certain purposes; and to give much more informed advice and help to the universities. These proposals should help the universities of Great Britain between them to cover as effectively as possible the whole field of university work. The old grant and most of any increased grant would still be given as a block grant to each university, and there would be no interference with the complete autonomy of the individual universities, either in the management of their own affairs or in undertaking new developments which they are able to finance from their general grant or in other ways.

It will be seen, therefore, that, contrary to the note issued by the British Association Committee, Sir Ernest leans to a reconstituted and strengthened University Grants Committee rather than to a universities' advisory council, nor does he appear to favour the formation of a separate body for the co-ordination of research, as is suggested in the report of the London Chamber of Commerce. There may well be considerable practical difficulties, as Prof. Field notes, in establishing any representative academic body of the type suggested by the British Association Committee without making it too large to function. The tributes uniformly paid to the work of the present University Grants Committee are further ground for believing that Sir Ernest Simon's proposals in his pamphlet are the most promising line of advance at the moment. Even if further machinery should ultimately prove desirable, there can be little doubt that the University Grants Committee, strengthened in the way indicated, should provide a large measure of the guidance and co-ordination that will be required in facing not merely the immediate post-war needs but also the ultimate and long-range problems of university expansion in regard to both teaching and research.

Not the least of the merits of Sir Ernest Simon's pamphlet is the way in which, in an appendix illustrating the need for national planning in this field, he sets forth the questions to which answers have to be found. Most, if not all, of these questions have been asked in recent books and reports already quoted. To some of them, notably in the report of the Association of University Teachers, answers have already been more or less tentatively given. To many of them, it is clear, some national body must supply the authoritative answer. Manchester and other universities are now facing many of these ques-

tions and seeking answers, but it is implicit in Sir Ernest Simon's pamphlet that guidance from a national body would not only be welcomed, but is indeed essential if appropriate action is to be secured. Such questions as the order of magnitude of university expansion, whether this is to be secured by expanding existing universities or by developing university colleges to university status, clearly cannot be determined by individual universities alone, nor can the regional problems and those of the extent and size of the different schools or fields covered at individual universities be considered without some regard to national resources.

These are all questions which require answers before any increased resources can be wisely apportioned. If there is to be no undue delay, if false steps are to be avoided which might impede progress at a later date, it surely appears wise to use machinery the competence of which, even if in a more restricted field, has already won respect, than to establish an entirely fresh organization for which support must be won anew. While that machinery is dealing with the immediate problems, there should be time to consider those more fundamental questions as to the ultimate functions of a university, the balance between professional and vocational training and training in citizenship and in leadership. and the place of the university in the society which it serves. In the long run, the answers to these questions must determine the content, the scope and the length of university courses and the status of the staff. No one, however, who has studied the quinquennial reports of the University Grants Committee can doubt the capacity or vision of that Committee or that, reconstituted, it could become a centre of stimulus and creative thought in those great matters to which many minds are turning with fresh hope and zeal. It may well be hoped that these reports will do something to stimulate among university graduates generally the interest and thought that must precede any attempt to remedy the conspicuous weakness of most modern universities in Great Britain—the slight opportunity for their graduates to express their opinions on conditions of university life and study, and to participate actively in university affairs.

A HISTORY OF EPIDEMIC DISEASES

The Conquest of Epidemic Disease

A Chapter in the History of Ideas. By Charles-Edward Amory Winslow. Pp. xiii+411. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1943.) 30*s*. net.

THE epidemic diseases occupy much of the space in medical treatises of the Early and Middle Ages. The reason is not far to seek, for plagues and pestilences were common and the resultant decimation of populations at regular intervals was terrifying and impressive.

The conception of the causes of epidemic diseases has varied from age to age. Dr. Winslow has portrayed in this book the evolution of thought and reasoning on epidemiology by giving extracts from the works of the principal participants in this long and unfinished study.

In the earliest times demons figured largely in the etiology of the diseases, and in the primitive races their influence is still largely credited. Out of this belief came the use of charms against disease, witchcraft and exorcism. Even in so-called civilized countries demonology and magic continue to this day to be widely practised, though often cloaked under other names. In 1929, at York in Pennsylvania, a man was murdered by another who wished to have a lock of his hair to use as a charm. The coroner in this case is quoted as saying, "At least half the 60,000 residents of the city of York believe in witchcraft and as for the county's rural population of 90,000, they not only believe in witchcraft, but guide the minutest details of their lives by it".

The next conception was that of the wrath of God, when disease was seen as a punishment for sin. In the Old Testament the propitiation of devils is forbidden. Under the heading of metaphysical medicine, the author illustrates such ideas as astrological influences, the doctrine of signatures, and repellency, or the sending away of disease by means of animate things.

It was not until the advent of Greek science that reasoning began to triumph over superstition. In the age of Hippocrates three major factors in epidemic disease were postulated. First, an epidemic constitution of the atmosphere; secondly, individual predisposition; and thirdly, certain diseases were recognized as contagious and association with the afflicted was known to be dangerous.

The reality of contagion was sharply brought to notice in the fourteenth century by the Great Plague, and the object lesson was reinforced by experience with leprosy and syphilis. It is interesting to note that the relation between plague and disease in rodents was described in early Hindu scriptures.

Hieronymus Fracastorius, as is his right, is given a chapter to himself in which are extracts from his poem on syphilis and from his more important work on contagion.

In the seventeenth century came the conception of animate contagion. Kircher postulated the theory of transmission of disease by living organisms. He was not the first in this field, but his ideas were more concrete than those of his more fanciful predecessors. Leeuwenhoek with his microscopes was also of this age.

After Sydenham and Mead comes Rush and his investigations of epidemics of yellow fever in the late eighteenth century in America. The nineteenth century filth theory of disease was the doctrine of miasms modernized. Sanitary and housing details of this age are described in horrid detail. The change from the miasmatic to the contagion theory of epidemic disease is illustrated by the works of Panum on measles, of Snow on cholera, and of Budd on typhoid fever.

Pasteur ushered in the modern age, and our knowledge of epidemic diseases was brought nearer to completion by an understanding of the carrier state and of insect hosts.

Dr. Winslow's scheme of unfolding this story through the medium of the words or works of the actors in the drama succeeds admirably in being at once easily readable and complete enough to serve as a useful book of reference. There is a full bibliography and index and the book is well bound and printed. J. MARSHALL.

MILK DISTRIBUTION

This Milk Business

A Study from 1895 to 1943. By Arthur Guy Enock. Pp. xi+243+xii—lii+13 plates. (London: H. K. Lewis and Co., Ltd., 1943.) 18*s*. net.

THIS argumentative book covers a wide field, a field almost as large as the milk industry itself; and as in the industry, so in the book, science and prejudice, sound sense and special pleading, clear vision and obscurantism, jostle one another. Although the author somewhat disarmingly assesses the book as an endeavour "to bring interesting and helpful things to light, and to aid in the movement for higher efficiency", and again "as a confession of faith from a convinced believer in the high value of milk", yet since substantial portions of the book are concerned with technical matters bearing on the important subject of the heat treatment of milk, it is legitimate to apply to these portions of the book the usual standards of scientific appraisal.

Mr. A. G. Enock has been interested in refrigeration problems, in the manufacture of dairy machinery and in dairy engineering generally for more than forty years. As a dairy engineer he has seen the development of heat treatment of milk in Great Britain almost from the beginning. He introduced some years ago a process which had been experimented with in the United States—the 'in-bottle' method of pasteurization. By this method, milk is heated to 'holder' pasteurization temperatures (that is, between 145° and 150° F.), and is run at that temperature into the bottles in which it is to be distributed. The latter are sealed and are then kept between the two temperatures for the necessary 30 minutes holding period before cooling. The resulting pasteurized product has remarkable keeping qualities, since post-pasteurization contamination of the milk, which frequently occurs (though it is not difficult to prevent) in ordinary pasteurization plants where bottles are filled with milk by a separate operation *after* pasteurization, is completely avoided.

From the consumer's point of view there is no doubt that this is an excellent method of heat treatment, but it has certain drawbacks from the distributor's point of view. Some of these have been overcome by Mr. Enock in his latest 'in bottle' plant, but this plant still occupies a great deal of space—a criticism that is applicable to most 'holder' plants—it has to run for the greater part of an hour before the first bottles are available for distribution, it is costly, and mechanical difficulties, though fewer now than formerly, are not yet eliminated.

Mr. Enock's main thesis is the supreme excellence of this particular method of pasteurization. He is not content, however, with making a good—perhaps too good—case for the method with which he has been so closely associated, but goes on to criticize rather bitterly the rival method—modern high-temperature short-time ('H.T.S.T.') pasteurization, in the development of which dairy engineers no less competent than himself have spent much effort and which is being used successfully in many parts of the world—on grounds which are sometimes dubious, and supports his arguments by *ex cathedra* statements some of which are ill founded. One of his principal grounds for criticism is that he considers that 'H.T.S.T.' pasteurization has been accepted, and the legal standards for it laid down, on an insufficient scientific basis. Actually the basis is a great deal wider than the ordinary reader of this book is told. The author scarcely refers to the large amount of American work on the subject, and makes little mention of British and Continental work. He may, of course, be unaware of the quantity of information, some of it unpublished, that had accumulated before the Ministry of Health laid down in 1941 the present legal standards for H.T.S.T. pasteurization. To suggest, as the author does (p. 140), without quoting evidence, that sinister influences affected the Ministry's decision, is of subjective rather than objective significance, and to state (p. 150) that there is no evidence to support the belief that H.T.S.T. pasteurization at the temperature and time now legally adopted (milk exposed to at least 162° F. for at least 15 sec.) accomplishes the destruction of disease-bearing organisms which may occur in milk is to contradict the facts.

It would not be fair to the author to leave the impression that the book is not ably conceived and ably written, or that it suffers from anything more serious than occasional lapses, though some of these lapses, if taken at their face value by the uninitiated, might have unfortunate consequences. For anyone with a knowledge of the dairy industry, the book's presentation and arguments cannot be other than interesting and entertaining and in part, as this brief review has demonstrated, provocative.

While a large portion of the book is given to the discussion of pasteurization methods, it also contains valuable data and observations on milk production, and a thoughtful chapter on the future of "this milk business". Biographical and autobiographical touches and extracts from private correspondence add a certain lightness and provide some basis for the rather quizzical title.

H. D. KAY.

GEOLOGY FOR ENGINEERS

A Geology for Engineers

By F. G. H. Blyth. Pp. viii+302+16 plates. (London: Edward Arnold and Co., 1943.) 21*s*. net.

ENGINEERING covers such a wide field that students find little time available for courses which are outside the main scope of its studies. It can be argued that it is of benefit to those pursuing any vocational training to study some subject which tends to widen their interests, and from this point of view geology has many advantages, since most engineers are brought face to face with its teachings in areas and countries to which their vocation leads them. For this purpose the subject should be presented in an interesting form relieved so far as possible from the jargon which has gathered around it, in common with every other scientific subject at the present day.

It is admitted, too, that some knowledge of geology is of direct assistance to civil and mining engineers, and in most engineering schools students are required to take a course in geology which is given by teachers in a geological department. This is quite proper, since only those instructors who have practical experience in the field can adequately present the facts and principles of the subject. It is not always, however, that in such courses the special requirements of the engineer are kept sufficiently in mind. A great deal of the content of the subject which is useful or essential for a geologist to know is of little interest to an engineer, and he feels that the time which he has to devote to it is largely wasted. It becomes for him one more subject to be crammed as best he can.

It is not possible to impart to an engineer such a knowledge of geology as will enable him to appreciate or deal with various geological problems that he may be confronted with in practice. He should, however, know enough to recognize when he is faced with a problem in which geological advice is essential.

Two thirds of this text-book is an elementary course of geology including petrology and mineralogy but excluding palæontology. It is presented in too condensed a form to serve as a cultural study and, on the other hand, is too abstruse to be of direct service to an engineer. It is difficult to see the usefulness to such a student of a knowledge of minerals like antigorite, axinite, celsian, dickite, to choose a few at random, or such rocks as brucite marble, wollastonite marble, teschenite or the deep sea red clay, or again such structures as the ring dykes and cone sheets of the west of Scotland. All such matter and much besides could well have been severely pruned in the interest of the engineer.

On the other hand, the section on the use and interpretation of geological maps could well have been expanded, though the best manner of imparting this knowledge is in practical classes, where actual geological maps on various scales are handled rather than the outline maps habitually used in the instruction of geological students.

Only the latter third of this book is devoted to certain aspects of geology as applied to engineering. These include the geology of water supply, of reservoirs and dam sites, and of cuttings and tunnels, which are well presented though they might with advantage be somewhat fuller.

It is noteworthy that only a minute fraction of the information contained in the first two hundred pages of the book is necessary in order to understand the section devoted to engineering problems.

Of late years, engineers have begun to be interested in a branch of civil engineering called soil mechanics, and in the applications of geophysical methods to engineering problems. Mr. A. W. Skempton, who is an acknowledged authority on soil mechanics, has contributed an appendix on this subject which is one of the most useful parts of the book. An appendix on geophysics is supplied by Dr. Bruckshaw, while a third appendix is devoted to a useful list of the publications of the Geological Survey of Great Britain.

O. T. JONES.

BRITISH TIMBERS

British Timbers
Their Properties, Uses and Identification; with Notes on the Growth and Cultivation of the Trees. By E. H. B. Boulton and B. Alwyn Jay. Pp. 112+31 plates. (London: Adam and Charles Black, Ltd., 1944.) 12*s.* 6*d.* net.

THIS book, with ninety-four pages of text, sixty drawings of transverse and tangential sections, and thirty-one plates showing the plain, quartered and transverse sections of British woods, should prove useful to architects, engineers, builders, and others who are employed or interested in the uses of timber. The little volume embraces all phases—from the seed to the mature tree and the timber.

The planting of trees in England, which in earlier years attracted the interest of a wide section of the people, insensibly diminished year by year until, as the authors say: "The extremely important part played by home-grown timbers in the world war has resulted in a revival of interest in our own woods, and an accompanying demand for information about them". The period between the War of 1914–18 and the present War witnessed an improvement in the public attitude, but not nearly of sufficient consequence to meet the terrible demands of the years 1939–44.

The qualities of British grown timber, and its uses, have been neglected for more than a hundred years. This book comes at a propitious moment, meeting a long-existing need.

The general unfortunate impression has prevailed that Great Britain cannot produce timber of useful quality to compete with foreign supplies. We now know this view to be wrong. The outcome of the debate in Parliament, and the report of the Forestry Commission, if they served no other purpose, at least emphasized the fact that as good and better timber can be grown in Great Britain as in any other country of similar climate. Moreover, many illustrations have emerged; for example, the quality of Scots pine (*Pinus sylvestris*) from one estate yielded prime clear boards free of knots, and of a texture equal to the best that has been seen from Finland, and approximating to the quality of Archangel. Douglas fir (*Pseudotsuga Douglasii—P. taxifolia*) can claim similar success in competition with that from British Columbia. Before this War there were few who would have thought it possible for aerial poles to be provided of a height of 95 ft., with a diameter of 9 in. at the top, and from trees not exceeding eighty years old, if as much, but this has been accomplished. Redwood (*Sequoia sempervirens*), of intrinsic quality, as good as that from California, has been grown; but the want of scientific practice of forestry has resulted in the tree producing too many branches, which means too many knots. In England the general lack of information, and the entire absence of this scientific practice for so many years, was partially responsible for the reluctance of the woodworking industry to employ home-grown timber. Perhaps a more serious feature has been the exceedingly high cost of transport, especially railway rates, which have operated differentially, to the disadvantage of home-grown timber. The authors deal with some of these questions, and afford an opportunity for the study and acceptance of an entirely new outlook.

The book contains eight chapters. Chapter 1, "British trees and their Cultivation", is a good outline in principle, giving a working basis for the amateur planter, with information as to type of soil, planting, etc. Chapter 2, on "The Properties of Wood", deals lightly with many aspects, including grain, moisture content, attack by fungi and beetles, durability, seasoning by air and kiln driers, etc. The chapter on the "Identification of Timbers commonly grown in Britain" contains some good diagrams, and should prove useful in identification, perhaps requiring the assistance and confirmation of the photomicrograph. The chapters dealing with "Hardwoods and Softwoods" are comprehensive and well condensed, giving useful and interesting information. While the plates are interesting, it is doubtful, having regard to the cost of production, whether they provide sufficient interest to warrant their inclusion.

Never before in the history of Great Britain have our woodlands been so fearfully devastated, and the first necessity with which we are confronted is their restoration. At the same time, we should learn from the experience of the last few years to adapt our methods so that our home-grown timbers may be employed to the best advantage.

THE NATURE OF THE VITAMIN B_2 COMPLEX*

By F. A. ROBINSON
Glaxo Laboratories, Ltd., Greenford

THE existence of an 'accessory food factor' was first established by Grijns in the Dutch East Indies, who showed that beri-beri is not due to an infection or a toxic agent, but to a deficiency of some factor in the diet, and in 1911 Funk proposed the name 'vitamines' for factors of this type, implying amines essential for life. Afterwards, the 'e' was dropped, when it was realized that vitamins are not necessarily amines.

In 1915, McCollum and Davis named Grijns' beri-beri factor 'water-soluble vitamin B', to distinguish it from the oil-soluble vitamin A, and in 1920 Emmett and Luros differentiated the true anti-neuritic factor, which was heat labile, from a heat-stable substance, which they assumed to be the pellagra-preventive factor; the substances were called vitamin B_1 and vitamin B_2 respectively.

The constitution of vitamin B_1, now known as 'aneurine' in Great Britain and 'thiamine' in the United States, was established in 1936, and the vitamin was synthesized in 1936–37. Liver, yeast and cereals proved to be particularly rich sources. Thanks mainly to the experiments of Peters and his co-workers, aneurine is now known to be concerned with the metabolism of pyruvic acid which otherwise accumulates in the body, and aneurine pyrophosphate is now believed to be the coenzyme, known as 'cocarboxylase', responsible for the conversion of pyruvic acid into lactic acid, though the reaction is almost certainly not a simple decarboxylation. Aneurine is specific in its action, and only a few closely related analogues show any effect on the growth of vitamin B_1-deficient animals.

Once the distinction between the anti-neuritic and pellagra-preventive factors was recognized, attention was directed to the nature of the heat-stable factor. The concentrates at that time available prevented pellagra in human beings, cured black-tongue in dogs, and a form of dermatitis in rats. They also increased the growth-rate of rats, and this property was used for estimating the vitamin.

A few years later, however, it was shown that the effect on the growth of rats was not due to the pellagra-preventive factor, but to a substance which Kuhn and his colleagues isolated in 1933 from eggs, milk and liver, and which they called 'lactoflavin'. It also occurs in yeast, and its constitution was established independently by Kuhn and by Karrer; on being shown to contain ribose, it was renamed 'riboflavin'. It was synthesized by both workers in 1934.

Riboflavin proved to be the prosthetic group of Warburg and Christian's 'yellow enzyme', known also as 'diaphorase', which is an essential link in the oxidation of carbohydrates. The enzyme appears to be riboflavin phosphoric ester linked to a protein carrier. As with aneurine, the association of riboflavin with an enzyme system probably accounts for its specificity, for only the arabinose analogue, and the ribose compounds with one of the methyl groups replaced by a hydrogen atom or ethyl group, possess vitamin B_2 activity.

* Substance of a lecture delivered before the Nutrition Panel of the Food Group of the Society of Chemical Industry on February 9.

Shortly after it had been established that the rat-growth method was not specific for the pellagra-preventive factor, chicks were proposed as test animals, and a concentrate that cured dermatitis in chicks was shown to cure black-tongue in dogs. In 1937, however, Elvehjem and Woolley isolated nicotinamide from a liver extract, and showed that it cured both black-tongue in dogs and pellagra in human beings, but was ineffective in the chick test. It is now recognized to be the prosthetic group of di- and tri-phosphopyridine nucleotide, both of which are dehydrogenases; the former, known as coenzyme I or cozymase, being a hydrogen carrier in sugar fermentation, muscle contraction and tissue oxidation, and the latter, known as coenzyme II, playing a similar part in the dehydrogenation of glutamic acid and glucose. Nicotinic acid proved to be as effective as its amide in the cure of pellagra and canine black-tongue, and a few closely related substances have similar activity. Quinolinic acid, however, and pyrazine-mono- and di-carboxylic acids appeared to be active in pellagra but not in black-tongue.

The recognition that nicotinic acid or amide was the pellagra-preventive factor left the nature of the rat and chick anti-dermatitis factors still unsolved. The rat factor, known as vitamin B_6, factor I or eluate factor, was isolated in crystalline form in 1938 by several groups of workers, and synthesized shortly afterwards; it is now known as pyridoxine. Although its function is unknown, its absence from a diet has always been associated with anæmia. Like other vitamin B factors, it is highly specific.

The chick anti-dermatitis factor, known as factor II or filtrate factor, proved unexpectedly difficult to characterize, pure concentrates not being readily obtainable. Eventually, however, β-alanine was identified as one half of the molecule and this, when combined with the other half, regen rated the active substance.

At about the same time as Grijns was making his observations on beri-beri, Wildiers demonstrated that certain strains of yeast would not grow on a synthetic medium unless a yeast extract was added, and he termed the responsible factor 'bios'. In 1922, Fulmer and Nelson showed that bios was a mixture of at least two substances: they were distinguished by Lash Miller as Bios I and II, and he was later able to show that bios was composed of seven or eight different substances. Bios I was identified by Eastcott as *meso*inositol, and afterwards three of the other bios factors were shown to be identical with vitamin B_1, nicotinic acid and pyridoxine. Bios II was separated into two components, one of which, the so-called 'Bios IIB', was shown to be identical with biotin, and the other, 'Bios IIA', was named 'pantothenic acid'.

The properties of pantothenic acid closely resembled those of the chick anti-dermatitis factor, and in 1939 R. J. Williams isolated β-alanine from pantothenic acid, and Jukes showed that it cured chick dermatitis; finally, it was shown that the chick factor was also a growth-factor for certain micro-organisms that required pantothenic acid. The constitution of pantothenic acid was established soon afterwards, and it was synthesized.

Although it is believed that pantothenic acid is essential for man, it is not yet known what function it performs; but, like the other vitamin-B factors, it is highly specific, and of the many analogues made, including several prepared by Dr. Barnett and the

present author, only one, hydroxypantothenic acid, showed marked activity. There is presumptive evidence, to be referred to later, that pantothenic acid may be a constituent of an enzyme system.

Bios IIB and Bios IIA had similar histories. In 1927, Boas-Fixsen observed a form of dermatitis in rats which had been fed on raw egg-white. This was prevented by a liver fraction afterwards studied by György, who called it 'vitamin H'. The purification of this factor proved to be extremely difficult because of the small amount present in even the richest sources, but it was eventually shown to be the same as biotin, that is, Lash Miller's Bios IIB. The factor in raw egg-white which caused dermatitis is now known as 'avidin', and has been prepared in crystalline form and shown to be a protein-carbohydrate complex. It combines with biotin to form an inactive complex.

The constitution of biotin was recently established, and its synthesis has been reported, though details have not yet been published. A few weeks ago du Vigneaud reported that methyl-imidazolone-caproic acid could replace biotin as a growth-factor for yeast, but not for *Lactobacillus helveticus* (*L. casei* ε).

One result of the investigations, especially in the United States, on the nutritional requirements of bacteria, has been the development of synthetic media in which substances of natural origin, possibly containing unknown growth-factors, are eliminated so far as possible. Such media are used for estimating the vitamin content of foodstuffs and biological tissues and extracts by comparing the growth of suitable organisms, when known amounts of the substance to be tested are added to an otherwise complete medium, with that of similar cultures containing known amounts of the pure vitamin. The use of such chemically defined media in place of media containing crude concentrates revealed the existence of new growth-factors previously unsuspected.

In this way R. J. Williams discovered folic acid, so called because it was first obtained from green leaves, though it is now known to be present also in liver, kidney and yeast. The preparation of pure folic acid has only just been announced, and its constitution is unknown. Concentrates are prepared by adsorption on charcoal, followed by elution and precipitation with lead and silver salts. The final stages of the purification and the properties of the substance have not yet been described. The factor is not only essential for the growth of *Streptococcus lactis*, the organism with which its existence was first demonstrated, but also for many other exacting micro-organisms.

A number of other factors have also been reported in the literature. Hogan and his co-workers, for example, claimed to have isolated by successive adsorption on fullers' earth, 'Superfiltrol', charcoal and 'Amberlite', a factor which they call vitamin B_c. This is essential for the growth of chicks, and was isolated as orange-yellow platelets, the analysis of which agreed with the formula $C_8H_{10}N_3O_3$. A similar factor, having a similar formula, was isolated by Stokstad.

Briggs, Lucky, Elvehjem and Hart obtained two water-soluble factors from liver by adsorption on 'Norit' and 'Superfiltrol'. These appear to be different from folic acid, and one of them, called vitamin B_{10}, was necessary for the growth of chicks, and the other, vitamin B_{11}, for the feathering of chicks. Another factor necessary for chicks was described by Hutchings.

New factors essential for the growth of micro-organisms have been described by Snell and Peterson, Müller and Miller, Peterson and Burkholder, and Happold and his colleagues. Snell, Guirard and Williams discovered a substance which they call 'pseudo-pyridoxine', since it appeared to be produced from pyridoxine; it is a potent growth-factor and interferes with the microbiological assay of pyridoxine.

Mr. Emery and the present author, working in collaboration with Dr. E. C. Barton-Wright, recently prepared from liver a factor which may be identical with folic acid, together with another factor soluble in chloroform, which stimulates the growth of *L. helveticus* and *S. lactis*; this second factor appears to be distinct from folic acid.

Our knowledge of the vitamin B_2 complex has also been extended by investigations carried out on sulphonamides. It was early recognized that sulphanilamide did not kill bacteria in the same way as the older antiseptics, and the clue to the now generally accepted mechanism of sulphonamide bacteriostasis was provided by Woods, who showed that sulphanilamide was antagonized by a fraction from yeast which had many of the properties of *p*-aminobenzoic acid, and by *p*-aminobenzoic acid itself. He put forward the theory that sulphanilamide owes its antibacterial effect to competition with *p*-aminobenzoic acid at the surface of an enzyme essential to growth.

Fildes suggested that *p*-aminobenzoic acid was an essential metabolite for all organisms that are inhibited by sulphanilamide, and pointed out that some sulphanilamide-sensitive organisms can synthesize their own *p*-aminobenzoic acid, which is, therefore, not a growth-factor for these particular organisms, but an essential metabolite. Sulphanilamide, therefore, acts by competing with an essential metabolite. *p*-Aminobenzoic acid is now known to be a growth-substance for a number of micro-organisms, and must, therefore, be regarded as a bios factor. It has also been shown to be necessary for the well-being of certain animals.

Another substance which antagonizes the effect of sulphanilamide is adenine; like *p*-aminobenzoic acid, it is also a growth-factor for certain bacteria. This may be associated with its presence in coenzymes I and II, referred to above, or in nucleic acids.

The essential metabolite theory of the mechanism of sulphonamide activity led to the discovery of other antibacterial substances which are active by reason of competition with growth-factors. Rubbo and Gillespie showed that *p*-aminophenylacetic acid is a growth-factor for *Clostridium acetobutylicum*, for which the corresponding *p*-aminophenyl methane sulphonic acid is a growth-inhibitor. McIlwain found that pyridine-β-sulphonic acid and its amide antagonize the action of nicotinic acid, and that the growth promoted by certain α-aminoacids is inhibited by the corresponding amino-sulphonic acids. Dr. Barnett and the present author, in conjunction with Dr. McIlwain, showed a similar relationship to exist between pantothenic acid and pantoyltaurine for *Streptococcus hæmolyticus* and certain strains of *Corynebacterium diphtheriæ*. The results suggest that pantothenic acid may be part of an enzyme system. Unfortunately, pantoyltaurine proved to be of little value in curing infections in experimental animals, as it was rapidly excreted, and its effectiveness was

educed by the pantothenic acid present in animal issues. A number of other derivatives recently prepared by Dr. Barnett and the author proved to be no more effective *in vivo* than pantoyltaurine.

Woolley and White have just announced that pyrithiamine', an analogue of aneurine in which the hiazole ring is replaced by a pyridine ring, will nhibit the growth of micro-organisms for which aneurine is an essential metabolite. The organisms that required the intact aneurine molecule were more sensitive than those that required only half the molecule, and these in turn were more sensitive to pyrithiamine than bacteria capable of growing in absence of aneurine.

Certain properties of sulphonamides are also linked with the vitamin B_2 complex in another and different way. Sulphaguanidine and succinyl sulphathiazole, which are now used as intestinal antiseptics, produced symptoms in experimental animals similar to those obtained with a diet deficient in inositol, pantothenic acid, biotin, folic acid or *p*-aminobenzoic acid; these symptoms were cured by feeding one or other of these factors. It was then shown that the sulphonamides were destroying intestinal micro-organisms capable of synthesizing these factors, and it follows from this that normal animals are dependent on the vitamins produced by their intestinal flora for maintenance of health. This explained the diverse symptoms that different workers had previously observed from a deficiency of one particular factor, and also why the absence of one factor may produce a multiple vitamin deficiency, for, whether the growth of the intestinal flora is depressed by the feeding of sulphonamides or by absence of one essential factor, a deficiency of several factors will result.

Recently, Najjar and Holt observed that a group of volunteers fed on a vitamin B_1-deficient diet did not develop vitamin B_1 deficiency but, on the other hand, actually excreted vitamin B_1; this was suppressed by administration of succinyl sulphathiazole. This appears to be the first indication that human beings can absorb vitamin B_1 from the intestine, and it raises the question whether other factors may not normally be provided in the same way. It also suggests that vitamin B_2 factors may have to be administered to patients under treatment with these sulphonamides.

Another substance frequently classified with the vitamin B_2 complex is inositol, the first of the bios factors to be recognized. This is now known to stimulate the growth of intestinal bacteria, and its absence also results in the development of fatty livers. Fatty livers are cured not only by inositol, but also by choline, and this substance is sometimes regarded as a member of the vitamin B_2 complex.

Choline takes part in the methylating activity of the liver, though it is not the only substance that can function in this way, and both methionine and betaine can serve as methyl donators. Substances, for example glycocyamine, exist in the body, which will accept methyl groups from methionine or choline; since the reaction is irreversible, this leads to depletion of the body reserves of labile methyl groups, and so to failure of the transmethylating mechanism. The connexion with fatty liver formation is not yet clear.

The use of liver extracts in the treatment of pernicious anæmia is well known, but the isolation and purification of the responsible substance has been rendered more difficult by the absence of a laboratory method of assay, investigators being dependent on clinical trials for following the progress of purification. In spite of this, marked advances have been made, and Karrer recently reported that a concentrate of the antipernicious anæmia factor containing only 35 mgm. of solid had given a clinical response. Mr. Hurran and Mr. Emery, in my laboratory, have now prepared a concentrate which gives an optima reticulocyte and red-cell response at a level of only 5 mgm. Whether the anti-pernicious anæmia factor should be regarded as a member of the vitamin B_2 group is still uncertain.

There is some evidence that for the cure of nutritional and tropical macrocytic anæmias, other substances in addition to the pernicious anæmia factor are required, but the nature of these factors is unknown. Certain experimental anæmias in animals respond to preparations not containing the anti-pernicious anæmia factor; a microcytic hypochromic anæmia in dogs, for example, responded to pyridoxine, and a normochromic normocytic anæmia was cured by a crude concentrate of pantothenic acid, whereas an anæmia and leucopenia in monkeys was cured not only by a liver extract, but also by an extract of brewers' yeast, which does not contain the anti-pernicious anæmia factor. The factor responsible was designated vitamin M, and Totter and Day recently found that it could be replaced partly, though not entirely, by xanthopterin, a purine-like substance first isolated from the wing-pigments of the brimstone butterfly. According to Simmons and Norris, it cures fish anæmia and goats' milk anæmia in rats.

Elvehjem cured an anæmia and leucopenia in monkeys due to administration of sulphonamides by means of a folic acid concentrate, and this has been confirmed by Daft and Sebrell, using pure folic acid.

It is evident from this survey that the substances which have been included, at one time or another, in the vitamin B_2 complex have widely differing chemical structures. Some of these substances, however, are not vitamins in the strict sense of the term; for historically vitamins are accessory food factors essential for the health of men and animals, and it has not yet been proved that vertebrates require some of the bios factors included in this discussion. Nevertheless, the components of the vitamin B_2 complex and of bios overlap to a considerable extent; most of the members of both groups occur in the same natural sources, especially yeast and liver, they are specific in their effects, and most of them appear to be associated with metabolic processes. Indeed, aneurine, riboflavin, nicotinamide and adenine are known to be prosthetic groups of enzymes, and there is a strong presumption that *p*-aminobenzoic acid and pantothenic acid are also constituents of enzyme systems.

It is quite possible that each of the other members of the vitamin B_2 complex may prove to be an essential part of an enzyme essential for the conversion of food into energy. This seems to be the only explanation of the fact that the same growth-factors are required by the highly organized vertebrates and by the very lowest forms of life; such factors must indeed be associated with the most fundamental of biological processes.

In view of the restricted meaning attached to the word 'vitamins', it seems desirable to have available another word to describe the group of substances now under discussion, which includes not only vitamins

as generally understood, but also essential metabolites, growth-factors, and possibly even amino-acids, for example, methionine, with specific actions. The word 'biotics' is now proposed for this purpose; like the word 'vitamins' it connotes 'essential for life', and, moreover, its antithesis, 'antibiotics', is now fairly well established, especially in the United States, to describe antibacterial substances produced by moulds and other micro-organisms.

The word 'biotics' could be used in a parallel sense to describe all substances of natural origin, and more particularly substances produced by micro-organisms, minute amounts of which are capable of stimulating the metabolism of living organisms and which are specific in their action, that is, not readily replaced even by closely related substances.

PROGRESS IN GEOGRAPHICAL METHOD

By W. FITZGERALD
University of Manchester

UNTIL the close of the nineteenth century, all attempts to construct a system of geography or to provide the subject with a distinctive philosophy were virtually confined to Germany and France. Down to the time of Herbertson, who was at Oxford early this century, there was remarkably little attention to the subject in Great Britain, and the investigations of even the most distinguished Continental geographers failed to arouse more than meagre interest in these islands. The exclusion of geography from the universities of Great Britain, until two or three decades ago, merits the notice of our educationists to-day, not so much because the development of the subject is significant to them, but because the conditions which deprived geography of fair opportunities for growth in nineteenth-century England are, to a considerable extent, still operative. This article is, however, not concerned with the position of geography in British education, but with those trends, in both method and concept, which have marked the development of the subject abroad, and particularly in Germany, from the late eighteenth century onwards.

Wherever geography is studied to-day, the systems employed clearly show the influence of Alexander von Humboldt and his contemporary, Karl Ritter. They were the acknowledged masters, in their respective fields, during the first half of the nineteenth century—'the classical period of geography', as it is known. Markedly different in outlook, they were yet complementary to each other, though most of the concepts they introduced originated in the thoughts of earlier German and French writers. In the first half of the eighteenth century there was much interest in the possible influence of environmental factors on the evolution of society. In particular, the ideas of Montesquieu expressed in "De l'esprit des lois" (1748) made a deeper impression than German geographers have been prepared to acknowledge.

Before the 'classical period' the place of geography within the body of knowledge was assessed according to the view taken of its practical utility, and particularly of its service in contributing to a full understanding of history. Even before the opening of the nineteenth century, however, there were those who wished to raise geography from its position of subordination to other studies and to make of it an independent science. Already there was widespread dissatisfaction with the political divisions of Europe as units of geography. For the purposes of geographical analysis such divisions, it was thought, should be replaced by 'natural' entities, with frontiers fixed and enduring. Theorization along these lines led to the first serious attempt to provide a partition of the world into regions: it was the work of the German geographer, Gatterer, in the period 1773–75.

Not widely known is the attention paid by Immanuel Kant to geographical investigations. His lectures on 'physical geography' at the University of Königsberg continued for forty successive sessions (1756–96). In his view, the organization of phenomena by classes divided Nature, without providing a coherent system, whereas 'physical geography', as he understood it, introduced the concept of unity to the study of man's environment. Two contrasted methods of geographical inquiry were already employed in Kant's day. One was the study of particular classes of phenomena in their distribution over the earth; the other involved relationships and interactions of many kinds of phenomena in particular regions of the world. The terms 'general' or 'systematic', for the first, and 'regional' for the second, were already coming into use. This early-established dualism, which still persists, has probably brought more confusion to geography than any other development in the method of the subject. In his 'physical geography' Kant was not limited to the environment of man: he was concerned with man also, as one of those agents of change which acted upon and modified the earth's surface.

The publication of the Africa volume, together with one of two Asiatic volumes, of "Die Erdkunde"[1], in 1817 and 1818, respectively, brought Karl Ritter to the forefront of geographical scholarship. To him more than to any other, with the possible exception of his friend and compatriot, Humboldt, is due the establishment of geography as an independent science. Moreover, his geographical interests and knowledge were more extensive than those of any previous scholar, as was recognized by an invitation to the chair of geography at the University of Berlin, then the only appointment of its kind in Germany, and the second in Europe. In "Die Erdkunde", a massive work, where history and geography meet in fruitful association, his main objective was to comprehend the influence of geographical factors on the social and economic development of society.

Comparison between Ritter and Humboldt emphasizes the much greater range of the latter's first-hand observations of natural phenomena, obtained through expeditions to Asia and America. In outlook and method they had much in common, though Humboldt was more concerned with the environment of man than with man himself. In the first of the five volumes of "Kosmos", physical geography was defined as a study of phenomena, arranged in areas, in their relations to all other phenomena with which they form a natural whole. While the so-called natural sciences study the forms, structures and processes of animals, plants and other phenomena, and seek to group them in classes or families according to their analogies, geography concerns itself only with these same phenomena as they occur together, related to each other within an area. No modern student of the subject has been able to add materially to this central idea in Humboldt's definition.

Though without immediate disciples, Humboldt exerted a much wider influence than Ritter, whose academic position, however, gave full opportunity for contacts with students. Elisée Reclus (1830–1905), more than any other, maintained the traditions of Ritter, as was shown by his exhaustive study, in nineteen volumes, of the regions of the world[2]. He provided the model and inspiration for the greatest of modern enterprises in regional geography, namely, "Géographie universelle", contributed by the most distinguished geographers of France, under the leadership of Vidal de la Blache. Among others indebted to Ritter for geographical training was Field-Marshal Moltke, founder of the German Imperial Army and the leading strategist of his time. Moltke undertook a variety of geographical studies, before concentrating upon geography in its relation to strategy—a study which has always commanded the respect of the German General Staff.

In Germany and France, therefore, the range of geographical inquiry was clearly comprehended by the closing years of the nineteenth century. Moreover, specialization within the subject had already begun, its first essay being the study of land-forms. Peschel, whose work appeared from 1866 onwards, was an early experimentalist in this field, though he extended his interests to an interpretation of the influence of the surface features of the earth on human activities. From his day down to the present, geomorphology has been accepted in Germany as lying wholly within the province of the geographer, and the fundamental basis of all his investigations. Yet it is undeniable that in Germany, as also in Britain and America, the majority of the principal contributions to the study of land-forms have come from men of science whose original interest and discipline was geological, however brilliant their incidental excursions into geography might be. In geomorphology the geologist and the geographer meet in effective partnership, but their respective contributions are complementary, not interchangeable.

Teutonic zeal for the science of land-forms proved to be infectious abroad, more particularly in the United States, where, through the agency of W. M. Davis, interest in the evolution of landscape spread widely. In view of their long apprenticeship in physical geography, American geographers should be encouraged to co-operate in a regional synthesis of land-forms, for the world as a whole. Such an enterprise is urgently needed, in order to supplement and modernize the world survey, largely geological in purpose, of the elder Suess[3]. Much of Europe and North America, not to mention other continents, has been covered by detailed geomorphological studies, and the material for such a work has long been accumulating.

The interests of the humanistic school of German geographers were maintained during 'the geomorphological period', as witness the studies of Friedrich Ratzel in the field which, quite inappropriately, he named *Anthropogeographie*. Ratzel's concepts had a wider appeal in Britain than those of other German geographers, which was the more unfortunate in that his work did not attain a standard of scientific scholarship equal to that of either Ritter or Humboldt. He was fortunate, however, in inspiring his gifted student, E. C. Semple, to undertake editorship and translation, with an Anglo-Saxon audience in mind[4]. Despite the title of his work, Ratzel was not concerned with the geography of racial distribution. His special interest lay in the response of man to environmental possibilities, and his name will always be associated with the earliest studies in the geography of States, that is, political geography.

Sufficient evidence is thus forthcoming for the co-existence, by the close of the nineteenth century, of two contrasted schools of geographical thought, the physical and the humanistic, respectively. Divergence of outlook was already so serious as to occasion deep concern to those German geographers who were determined to preserve the unity of their subject. In this connexion the distinguished contribution of Alfred Hettner, the most consistent and active student of geographical method in Europe during the last half-century, is particularly important. His authority to speak on the legitimacy of recent trends in geography was virtually unchallenged just before the present War[5].

Hettner insisted, early this century, that for the geographer the map is the essential means of expression. In 1905, he claimed that the development of cartographic methods had advanced so far that verbal description in geography had lost its original importance, and was useful merely to assist in the explanation of maps. To Hettner and others of like mind the quality of a geographer's contribution depends largely on the effectiveness with which he employs his cartographical technique. As the American geographer, James, has it, that contribution depends upon an "application of the technique of mapping distributions, and of comparing and generalizing the patterns of distribution"[6].

Of all Hettner's contributions to the progress of geographical method the most significant is associated with the idea of the 'region'. Like others of his time—Passarge and Herbertson are notable examples—he constructed a regional system which he regarded as essential to the organization of the study of the earth as the home of man. More thoroughly, however, than any of his contemporaries, or predecessors, he has investigated the theoretical requirements for such a classification of regions, and his is the only system which, in both conception and practical use, endeavours to associate, not only one or two criteria—such as climate and vegetation—but all the major factors of environment which are significant to mankind. At the same time, Hettner does not fall into the error of regarding regional divisions as a part of terrestrial reality: for him their validity is always subject to challenge. As he readily admitted, the difficult question as to which criteria should be selected for the determination of regions finds no answer in Nature. The choice is made by "the geographer, according to his subjective judgment of their importance. There is no universally valid regional division which does justice to all phenomena: we can endeavour only to secure a division with the greatest possible number of advantages and the least possible disadvantages". Hettner's classification of regions was published for the first time in Spamer's Atlas of 1897: completed and revised, it appeared later in two volumes as "Grundzüge der Länderkunde".

Of all the problems in geographical method, that which turns on the validity of the criteria employed in regional classification has aroused the most vigorous discussion. Recently it has stimulated the younger school of geographers in Britain, though the criticisms brought forward, up to date, have been more important on their negative than on their constructive side. The chief difficulty in attaining a

regional classification acceptable to the strictest canons of geographical method, results from some remaining uncertainty as to the place of man within the frontiers of geography. It is an old problem, but attention to it is more persistent and active than ever before, and the geographical schools of North America deserve the respect of their European colleagues for outstanding contributions to its solution. In the United States, discussion of method in geography is now much more purposeful than elsewhere. There we see the growth to very productive maturity of several particularly competent philosophers of geography. As an analysis of doctrine Hartshorne's recent work—"The Nature of Geography" (1939)—is probably without precedent in the history of the subject.

For the future the prospects of geography in Britain seem particularly bright, and for two main reasons: first, the subject has now a trained personnel of university rank, out of all proportion to the meagre team which was working at the beginning of the century, when only one chair of geography existed in Britain; secondly, attention to geographical principles and perspective is now recognized as essential to the political and economic planning, which are so desperately needed by an exhausted world.

Events of the last thirty years have brought the realization that planning along exclusively national lines, outside an international system, is completely abortive. Although the practicability of regarding the world as the unit of political and economic reconstruction has not yet gained general acceptance, a continental area has already proved to be a unit which is administratively possible, as witness the United States and the U.S.S.R. Ideas concerning the organization of territory and its population, in the interests of mankind as a whole, belong to the normal stock-in-trade of the geographer. Whatever may be the mistakes with which he is charged, the geographer certainly cannot be accused of parochialism of outlook.

In the interests of the academic prestige of his subject, it would be opportune for the geographer to undertake highly specialized regional research corresponding to the detailed investigations, into the events of very restricted periods of time, which are usual to the specialist historian. The monographs on the regions of France, contributed by Vidal de la Blache and his distinguished school, provide the model for similar studies on the regions of Britain. (How often have we to deplore that there is not in existence a scholarly, and at the same time comprehensive, published study of the geography of our own country.) A similar policy is not to be recommended, however, for the teaching of geography, except towards the close of the university course, when specialization is not likely to disturb the student's perspective. On the other hand, no honours school of diminutive staff should so disperse its teaching resources as to provide instruction in every phase of the subject.

A FISH-FARMING EXPERIMENT IN A SEA LOCH

By Dr. F. GROSS and J. E. G. RAYMONT
Department of Zoology, University of Edinburgh
AND
Dr. S. M. MARSHALL and Dr. A. P. ORR
Marine Station, Millport

Introduction

IN 1941 it was suggested in NATURE[1] that it might be possible to increase our food supply by increasing the fertility of suitable parts of the sea, and a scheme for a preliminary investigation was outlined. It was based on the assumption that the fertility of the sea is largely dependent on the same factors as that of the land or of freshwater fish ponds, namely, light and plant nutrients, and that an improvement could be obtained by supplementing with artificial fertilizers the amount of nutrients available for plant growth. Of these, nitrate and phosphate are known to limit the growth of phytoplankton in the sea, and it was assumed that the addition of sodium nitrate and superphosphate would lead to: (1) a higher level of plankton productivity; (2) a greater density of bottom fauna; and (3) an increased growth-rate of fish. (After we had started our work we found that the effect of fertilizers on the first link in this chain had been tried out in oyster polls in Norway so early as 1908, but no results were published until the fertilization experiments of Gaarder and Spärck in 1932[2,3]. They found that the addition of dissolved phosphorus and nitrogen in 5–10 times normal winter sea values led to an increase in nano- and zoo-plankton and also to a good growth of oyster larvæ.)

An experiment on the lines suggested was made possible by a generous offer of financial assistance from Imperial Chemical Industries Ltd., Billingham, which has led to a very active and stimulating co-operation. Acknowledgment of much valuable help and encouragement received from many other quarters will be included in a full account of our experiment which we hope to publish in the near future.

Our investigations were started two years ago, and until July 1943 observations and collections of samples were possible only during visits over week-ends and university vacations. Since then Mr. S. R. Nutman and Mr. D. T. Gauld have joined our team, and have been responsible for the collection of a considerable proportion of our data and results.

Hydrography and Fertilization

The site chosen for the experiment was Loch Craiglin, a small arm of Loch Sween, Argyll, covering an area of about eighteen acres, and connected with the large northern arm of the loch (Sailean More) by a narrow channel. A dam with a sluice was built across the channel; but as the dam was by no means watertight a considerable amount of water exchange took place between Loch Craiglin and Sailean More, particularly at high tides. The volume of the loch is some 70,000 cubic metres; its maximum depth about 5 metres, with an average depth of 1–2 metres.

The hydrographic conditions resemble closely those of the Norwegian oyster polls, which show much greater variations than the open sea. The salinity in deep water varied from 29 to 30 per thousand, which

is only a little below that of the open loch, while at and near the surface there was water of low salinity (9–28 per thousand). The temperature during most of the year was well above that of the open loch (maximum 22° C.).

During summer the abundant growth of green algæ (Cladophora and Enteromorpha) caused oxygen supersaturation and pH values of 9 and more, except in deep water where free hydrogen sulphide was present during the autumn and winter and where pH values of 7 and less were recorded. The water varied from brown to green in colour owing to suspended and dissolved matter, and at times more than 90 per cent of the incident light was absorbed by the upper $\frac{1}{4}$ m. layer.

Fertilizers were distributed in Loch Craiglin on ten different dates during the first year, beginning in April 1942. Altogether some 600 lb. sodium nitrate and 400 lb. superphosphate have been added, equivalent to 45 kgm. nitrogen and 17 kgm. phosphorus, that is, about five times and ten times their respective maximum winter values in the Clyde sea area. In the second year the amount of sodium nitrate was doubled at each fertilization, and by the beginning of this year another 600 lb. of nitrate and 200 lb. of phosphate have been added.

Utilization of the added fertilizers in the well illuminated layers was extremely rapid. On several occasions when fertilizers were distributed, only traces could be found in deeper water a week later. Day-to-day observations by Mr. Gauld showed that even when the values were increased to about four times maximum winter sea value, the dissolved phosphorus was completely removed in about four days.

Plankton

The most marked effect of the added fertilizers was on the so-called μ-flagellates, a much neglected group of autotrophic organisms, about 1–10 μ in size, which undoubtedly play an important part in the economy of the sea, by providing the bulk of the food for larval forms of copepods, lamellibranchs, etc., and part of the food of adult 'filterfeeders'[4,5,6,7].

Thus on December 30, 1942, one day after fertilization, the average number of μ-flagellates was 1,600 per cub. mm.; three days later it had risen to 3,900, five days later it was 3,100. On January 31, the highest population density for the year with more than 8,000 per cub. mm. was reached, as compared with the maximum density of 2,000 for Sailean More. Since the rise in μ-flagellates ran parallel to the depletion of nutrients, it appears that at least a large fraction of the dissolved fertilizers was rapidly taken up by, and converted into, μ-flagellates.

Fertilization had a less immediate effect on the diatoms and dinoflagellates. The spring diatom increase began in the middle of February, just after the deeper water in Loch Craiglin became stabilized, and lasted for several weeks. Diatoms were scarce during the summer but reappeared when the loch was fertilized again in September, and rose to high figures after the November fertilization. Minute species of Chaetoceros were responsible for both spring and autumn increases, when the maximum numbers averaged more than 7,000 cells per ml. from surface to 3 metres.

The most marked characteristic of the larger phytoplankton was the abundance of small thecate photosynthetic dinoflagellates, chiefly *Prorocentrum micans* and *Peridinium triquetra*. They were present throughout the year and the second rose to extraordinarily high numbers during the autumn and winter, reaching a figure of 1,600 per ml. in December.

In spring, fertilization had no apparent effect on any of the phytoplankton organisms, partly owing to the abstraction of nutrients by the actively growing shore algæ (Enteromorpha and Cladophora) and partly because of the grazing of a very large zooplankton population.

The zooplankton was characterized by a rich period early in the year, from March until May, and a rather poor period from summer until the end of the year. Copepods, of which Oithona and Acartia were the most abundant forms, rotifers and lamellibranch larvæ made up the bulk of the zooplankton.

When compared with the unfertilized water of the open loch (Sailean More) the plankton was found to differ in several ways and was almost always considerably richer. On the whole, Loch Craiglin, under the conditions of fertilization, ranks among the richest plankton areas known.

Bottom Fauna and the Food of Flatfish

The density of the bottom fauna showed great variations in different areas even before fertilization began. An extremely poor zone in the deeper region occupied about a quarter of the total area of Craiglin, while along the shallow eastern shore and southern bay a dense population flourished. The commonest animals were Chironomid larvæ, Hydrobia, Cardium, Oligochætes, Gammarus, Idothea, Nemertines and Capitellids, Chironomids being predominant.

If the populations at five sampling stations (two of which lie in the very poor zone) are averaged, we find that over the bottom of the whole loch the post-fertilization summer density had increased by 150 per cent over the winter pre-fertilization value. This increase might be regarded as an effect purely of summer reproduction, but the density of the bottom fauna would have been much greater but for the introduction of more than 3,000 flatfish, which, in addition to a large population of native small fishes (gobies, sticklebacks, etc.), greatly reduced the bottom population.

In the following winter (1942), the bottom fauna declined sharply owing, presumably, to the cessation of reproduction and to the continued feeding of the fish. Yet by the following summer (August 1943), despite the additional grazing depredations caused by a further stocking with 22,000 flounders and by the greatly increased numbers of small native fish, the average density of bottom fauna had increased by 240 per cent over the previous post-fertilization summer value. Furthermore, this great population only showed a slight decline during the autumn, and thus, in contrast to 1942, a great 'standing crop' of bottom fauna was maintained.

Some animals (Crustacea and Cardium), which showed no rise in population during the first summer, showed a spectacular increase in 1943.

An approximate calculation for the dry organic weight of the bottom fauna indicated that the fauna 'useful' as food for flatfish showed an increase in weight by August 1943 of 215 per cent over the previous summer value.

An analysis of the macroscopic organisms present in the alimentary canals of flatfish caught in Loch Craiglin showed that while plaice fed almost exclusively on Cardium, Hydrobia and polychætes, flounders were more general feeders. Flounders showed an average of 190 organisms per gut during winter. This intensive feeding was correlated with

good winter growth. The average weight and number of animals consumed increased during spring, reaching a maximum of 1,520 organisms per gut in June, when Chironomid larvæ formed almost 100 per cent of the food. A decline in feeding occurred during summer, although there was an abundance of food, and at the same time young Cardium became progressively more important in the diet, making up 70 per cent of the total food by October.

Growth of Plaice and Flounders

Between April and July 1942 some 2,700 small flounders and 600 plaice were transplanted to Loch Craiglin; of these, 425 plaice, 9–29 cm., were marked with numbered disks. The remaining 175 of a size less than 9 cm. were left unmarked. Fishing in Loch Craiglin presented great technical difficulties, caused by the nature of the bottom, and the number of recaptured fish during the first year, that is, by April 1943, was relatively small, namely, 57 (13·4 per cent) marked plaice, 32 (18·3 per cent) unmarked plaice, and 108 (4 per cent) unmarked flounders. In addition 11 flounders, varying from 20 to 30 cm., were caught, obviously 'native' fish which had been in the loch when it was dammed off.

The great majority of the marked plaice recaptured had their disks torn out. On the whole they have grown well in Loch Craiglin but not strikingly better than under natural conditions, the main reason being the profound setback received from marking.

The majority of unmarked plaice belonged to age-group I, that is, they were a little more than a year old when transplanted. The average length of the lot put in was 7·5 cm., the average weight 4·5 gm. In July 1943 their length was 22 cm., weight 117 gm. This represents an increase in length of 14·5 cm. or nearly 200 per cent and an increase in weight of 112 gm. or twenty-five times their original weight in about one year and one month.

In the North Sea the annual growth increment of plaice varies between 3 and 6 cm.[8,9,10]. The unmarked plaice in Loch Craiglin have thus accomplished 2–3 years' growth in a little more than a year. They were closely approaching the growth-rate of plaice transplanted to the Dogger Bank[11] and Limfjord[12], that is, areas characterized by an exceptional abundance of food animals and a sparse fish population.

Flounders transplanted in July 1942 from Loch Killisport had an average length of 3·4 cm. and 0·5 gm. weight. The same year-class in Loch Killisport reached a size of 5·1 cm. and 1·5 gm. in September and added only very little to their size by next April. At this time the flounders in Loch Craiglin had reached an average length of 11·8 cm. and a weight of more than 20 gm. During the first year they have grown about four times as fast in length and sixteen times as rapidly in weight as the Loch Killisport flounders.

During April–May 1943 we transplanted more than 1,000 one-year old flounders, and in July more than 21,000 flounders of 0-Group into Loch Craiglin. Although the fish were preyed upon by eels and cormorants, the new stocks increased the fish population, at least temporarily, to 1,000 fish per acre.

In spite of the much greater competition for food, our original flounder stock continued to grow very rapidly and reached an average size of 25·0 cm.–197 gm. by October 1943.

The annual growth increments of flounders growing under natural conditions in the Baltic—and what figures are available concerning their growth in Scottish waters are of the same order of magnitude—are about 5 cm. to begin with, declining to about 3 cm. in the fifth and sixth year[13,14,15]. The flounders in Loch Craiglin have thus completed a growth of 5–6 years in less than two years. The growth of the flounder stocks transplanted in 1943 has so far been equally satisfactory.

Both plaice and flounders, marked and unmarked, showed a remarkable growth during winter, amounting to a weight increase of 35–97 per cent during the period November 1942–April 1943. Thus the cessation of growth of fish on normal grounds during winter seems to be largely due to scarcity of fish food and not so much to climatic factors.

Conclusions

Our assumptions regarding the beneficial effect of fertilizers, through a complex food chain, on fish growth have proved correct. Moreover, the extremely rapid utilization of the fertilizers has opened up new possibilities: marine fish farming need not, perhaps, be confined to dammed off or very sheltered parts of the sea as we thought two years ago.

Our results strongly suggest that the excessively low productivity of the sea as compared with the land and as expressed in the low rate of both survival and growth of fish, is ultimately due to the scarcity of plant nutrients, that is, of nitrogen and phosphorus. Application of fertilizers, combined with hatching operations, might become a practical means of improving the yield of inshore fisheries, and lead to a future when fisheries will follow the path of agriculture; when development and production will take the place of conservation and restriction.

CENTRIFUGAL VACUUM FREEZING

ITS APPLICATION TO THE DRYING OF BIOLOGICAL MATERIALS FROM THE FROZEN STATE

By R. I. N. GREAVES

Drying Unit, Medical Research Council

MANY biological materials can be most conveniently preserved in one way only, namely, if they are dried from the frozen state. The success of the 'freeze-drying' procedure appears to be chiefly related to the fact that the resulting 'solid state' prevents the concentration and aggregation of the molecules of protein which, when they are dried from the liquid state, leads to their denaturation. The temperature of drying is of little importance provided it is below the eutectic point of the material and so

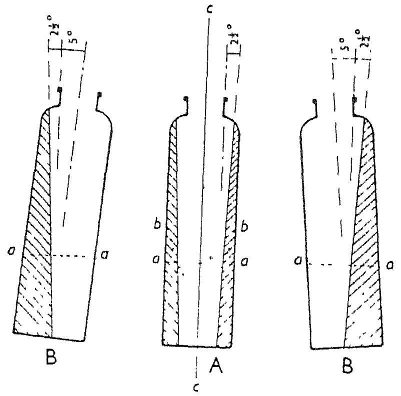
causes the solid state to be maintained throughout the period of desiccation. Moreover, on slow freezing, concentration of proteins and salts takes place. Therefore, to get the best dried product, particular attention must be paid to the freezing of the solutions.

In order that drying may be accomplished in a reasonable period of time, it is necessary to carry out the process in a high vacuum with adequate provision for the removal of the water vapour evolved. Under these conditions evaporation can be made so rapid that a liquid will freeze and the frozen material will drop in temperature unless the heat lost by evaporation is replaced. The speed of drying depends on the rapidity with which the heat lost can be replaced without causing the fusion of the frozen material.

When a protein solution is subjected to a high vacuum, it froths and bubbles violently before freezing with extreme suddenness. Although such a rapid freeze gives an ideal dried product, the method has grave limitations owing to the excessively large size of the container which must be used if the material is to be prevented from escaping. Hartley[1] has shown that this frothing is largely due to the liberation of the dissolved gases under reduced pressure, and that quiescent fluids can be obtained if these dissolved gases are first removed by a carefully controlled slow reduction of pressure. Greaves and Adair[2] and Flosdorf and Mudd[3] made use of this method of 'degassing' for obtaining quiescent solutions which could then be 'snap-frozen' and dried from the frozen state, if the pressure was suddenly reduced below the critical level. This method has been widely used, but it has certain disadvantages; for example, small quantities tend to dry from the liquid state during 'degassing', freezing tends to be somewhat erratic and unless the 'degassing' has been very thoroughly carried out some of the material may explode on freezing and be lost.

The alternative is to pre-freeze the material and introduce it frozen into the vacuum. Pre-freezing must be rapid in order to avoid concentration and obtain a good dried product; this procedure involves either low-temperature baths of 'dry-ice' or the vertical spin-freeze technique of Greaves[4], which is carried out in a current of cold air at $-18°$ C. Pre-freezing is convenient when drying large amounts of material distributed in big individual doses. With small doses there is a danger that partial fusion may occur before the necessary degree of vacuum is attained unless provision, with the resulting complications of manifolds or refrigerated heater heads, is made for keeping the ampoules refrigerated during this period. Consequently although since the outbreak of war great advances have been made in the large-scale drying of transfusion fluids in large individual doses, there has been little attention paid to the drying of large numbers of small doses, or to the small-scale drying of material which from time to time the laboratory worker may wish to preserve.

If frothing could be absolutely controlled, then the vacuum snap-freeze would be the method of choice for the drying of small doses. The previous endeavours to solve this problem have been along the lines of controlling the bubbles after their formation. From a physical point of view, however, a bubble is most vulnerable at its birth, and it occurred to me that some quite small force working against bubble formation might be sufficient to inhibit entirely its formation. For this reason the possibilities of centrifugation were investigated and it was found that quite slow speed, for example, 1,450 rev./min. with a



A. Bottle spinning on its vertical axis; liquid distributed round the periphery.
BB. Bottles spinning "off centre" inclined at an angle of 5° from the vertical; liquid distributed as a wedge on one side of the bottle.
aa. Original level of the liquid.
bb. Early stage in formation of cone as liquid gathers speed.
cc. Axis of rotation.

The angle of the final liquid surface from the vertical depends on the speed, and is approximate only.

minimal radius of 1 inch was more than adequate to inhibit the formation of bubbles in liquids *in vacuo*, although under these conditions existing bubbles were not destroyed. Various protein solutions have been subjected to high vacuums while spinning and all have 'snap-frozen' most uniformly without the slightest trace of bubble formation.

The centrifugal force has another use in that if the ampoule or bottle is spun on its vertical axis a cone is forced down through the liquid, thus distributing it round the inside periphery of the bottle, in which position it freezes and thus exposes a maximum surface for evaporation during the drying process (Greaves[4]). Obviously, the mechanics for accomplishing this condition for large numbers of ampoules would be difficult, but since quantities of 10 ml. or less if frozen as a wedge on one side of the ampoule would expose quite an adequate surface for drying, this condition can be accomplished much more simply by spinning the ampoules off centre and inclined at an angle of 5° from the vertical (see diagram). Thus in an apparatus of the type described by Greaves and Adair[5], several large disks drilled out to accommodate numerous ampoules can be spun on a common central shaft, the heat required for drying being transmitted by radiation from a heater-winding wound on a reflector screen below each disk.

This method has been applied extremely satisfactorily to the drying of sera and plasma, and is particularly suitable for the drying of 'complement'. Broths and crude penicillin solutions, which frequently prove difficult to dry by other methods, since they possess fractions which remain liquid at low temperatures, have been successfully handled by keeping the centrifuge running until the temperature of the material was low enough for this second component to be frozen. The method has also worked well even with very small quantities, for example, quantities so small as 1/40 ml. have been dried successfully from the frozen state; but with these very small quantities it is necessary to attain the requisite vacuum rapidly or there will be a tendency for them to dry out from the liquid state. For small quantities, phosphorus pentoxide has been used as a desiccant,

and for large amounts a mechanically refrigerated condenser.

Presumably the principle of preventing frothing by centrifugation could be applied also to many types of vacuum distillation in which frothing and bumping prove troublesome.

OBITUARIES

Sir Cecil Harcourt-Smith, K.C.V.O.

CECIL HARCOURT-SMITH was born on September 11, 1859, and died on March 27, 1944. In a long career he combined the tastes and studies of a classical scholar, an archæologist, and a connoisseur of medieval and Oriental art, with great ability as a Civil servant and administrator. His father, William Smith, was a solicitor. From a school at Brighton he was elected a scholar of Winchester College in 1873, but instead of passing on to university life, he entered the British Museum in 1879, in the Department of Greek and Roman Antiquities. His tastes were indeed already formed, and gained opportunities for advanced study on a broad programme, which would in those days have been difficult to achieve at college. His school contemporary, Arthur Hamilton Smith, who was his successor as keeper of his Department in the Museum, only arrived there seven years later, by way of a Cambridge degree and a fellowship.

For a while Smith's work was mainly in classical archæology. He was an active member of the Hellenic Society and of the Classical Association, and one of the founders and first editors of the *Classical Review*, which profited greatly by his wide interest in antiquities. But in 1887 he was attached to a diplomatic mission to Persia, and made ample use of this chance of studying a great tradition of Oriental art in its own surroundings. A second exceptional opportunity for field studies came in 1896, when the British School of Archæology at Athens was recognized by a Treasury grant, and it was thought wise to give it temporarily the experience of a Civil servant as director. This position he held for two sessions with great benefit to the School. Two fresh adventures were successfully launched, the *Annual*, a substantial budget of contributions to knowledge by the senior students and former students, and the memorable excavation of the prehistoric town at Phylakopi in Melos, the first inhabited site in Greek lands to be so revealed since Schliemann's work at Hissarlik, Mycenæ, and Tiryns. It was not Smith's fault that publication was delayed until 1904, by which time its significance was eclipsed by far larger achievements at Knossos. But Phylakopi has its distinguished place in the perspective of Aryan archæology, and in the British contribution to it.

During these years, Smith was promoted assistant keeper in the Museum, and became keeper in 1904. His principal publication there was the volume of the great "Catalogue of Greek Vases", dealing with the earlier Greek styles ; his preliminary work on the prehistoric pottery was interrupted by the Museum's own excavations in Cyprus, which brought in a very large contribution to the Late Minoan section, as well as to the pre-Minoan and Early Iron Age series.

Meanwhile, Smith had been extending his experience of archæological administration both at home and abroad, and in 1908 he was appointed chairman of the Commission to consider rearrangement of the Victoria and Albert Museum, which had completely outgrown both its accommodation and its original function as an appendage of the old Science and Art Department ; and its relations with the British Museum had never been satisfactorily defined. Here Smith's knowledge, tact and initiative created a new order, and it was an obvious sequel that he should be the new director and secretary, to give effect to his Committee's proposals. From 1909 until 1924, the Victoria and Albert Museum prospered under his guidance. Valuable objects were secured, such as the Salting collection, the Rodin sculptures (later transferred to the Tate Gallery), the Alma Tadema library, and the Pierpont Morgan stained glass. A great series of catalogues was prepared by an enlarged, better trained, and better paid staff ; space was provided for students throughout the Museum, and especially in the library ; official guides and reproductions were organized, and special exhibitions arranged from time to time.

With so many interests, and personal gifts, Smith led a busy life, and recognition came in due course : knighthood in 1909, C.V.O. in 1917, and K.C.V.O. in 1934. After retiring from the Museum, Sir Cecil became adviser in 1925 for the Royal Art Collections, and in 1928 surveyor of the Royal Works of Art. His medieval interests made him a leading member of the Central Committee for the Care of Churches, and the Incorporated Church Building Society. The Franco-British Exhibition of 1921 was in great measure his work. He was secretary of the Society of Dilettanti and brought out its "History" in 1932, and a constant friend and counsellor of collectors and colleagues at home and abroad. His personal charm, eloquence and skill in languages made him a valued member of committees and congresses of many kinds ; and in these social activities his accomplished wife gave him unfailing support. Grateful acknowledgment must be made of his constant and sympathetic encouragement of younger people. Few men had their knowledge available so promptly or so generously.

JOHN L. MYRES.

Dr. A. W. Pollard, C.B., F.B.A.

ALFRED WILLIAM POLLARD, who died on March 8, aged eighty-six, had lived for some years in retirement, but bibliographers and students of literature will find it hard to believe that he is dead, so vivid was his mind and so fertile his work.

The son of a London medical man, Pollard was educated at King's College School, then still in the Strand, and at St. John's College, Oxford, where he was placed in the first class in Mods. and, unlike his friend and fellow-scholar Housman, also in Greats. In 1883 he was appointed an assistant in the British Museum Library, some other possible professions being barred by a bad stammer, and thus the nature of his life-work was determined.

An early marriage made extra work necessary, and the material was at his hand in the Museum. He helped Dr. Furnivall with the Early English Text Society's transcripts of Chaucer manuscripts, reviewed for the *Guardian* in its great days under D. C. Lathbury, edited Herrick and a collection of "English Miracle Plays", while his work on Chaucer bore

fruit rather later in the Globe edition of the "Works" and a "Primer".

In the Herrick, a taste for fine (not necessarily luxurious) book production was already visible, and in the Museum Pollard was already becoming recognized as the Library's expert on typography. In the same year (1893) this side of his activity was given fresh impetus by two events. Robert Proctor joined the Library's staff; in the next ten years Proctor was to put the history of the first fifty years of printing on a new basis, and Pollard learned much from working with his younger colleague, whose work he completed by founding the Museum's great catalogue of incunabula. He became honorary secretary of the newly founded Bibliographical Society, a post he was to hold until 1934, ten years after his retirement from the keepership of printed books in the Museum. For those forty years Pollard directed the Society, and with the help of Proctor, R. B. McKerrow, Dr. W. W. Greg and other scholars used it to produce a large body of valuable contributions to the bibliography and history of literature, particularly English literature of the fifteenth, sixteenth and seventeenth centuries.

Another special study of his was the English Bible, of which he published a volume of "Records" in 1911, the fruit of the Museum's exhibition at the tercentenary of the Authorized Version. But he is best known, perhaps, by his application of bibliography to the text of Shakespeare. He published his "Shakespeare's Folios and Quartos" so early as 1909, and followed it up with other publications, culminating in his British Academy Lecture, "The Foundations of Shakespeare's Text", in 1923, suggesting a new and fruitful method, which has been well used by Prof. J. D. Wilson and others.

In 1887 Pollard married Miss Alice England, of Newnham College, who predeceased him. They had two sons, both of whom were killed in the War of 1914–18, and a daughter, who survives him. Those who knew him at the time of his great loss found his noble bearing an inspiration; it deepened the affection and respect in which he had always been regarded in and outside the Museum for his great talents, his industry, his warm heart and his lofty and religious nature. ARUNDELL ESDAILE.

Prof. A. E. Jolliffe

ARTHUR ERNEST JOLLIFFE, who retired from the professorship of mathematics in the University of London (King's College) in 1936, died in Oxford on March 17, 1944. He was educated at Balliol College, Oxford, won the Junior and Senior University Mathematical Scholarships and, shortly after taking his degree, was elected to a fellowship at Corpus Christi College, Oxford, in 1892. After a year at Lampeter as lecturer, he returned to Oxford as mathematical tutor at Corpus, a post which he held until 1920. He was then appointed professor of mathematics at Royal Holloway College, from which he proceeded to the professorship at King's in 1924.

Jolliffe was one of the outstanding mathematical tutors of his time. On his return to Oxford in 1893, he at once devoted himself wholeheartedly and with complete selflessness to the interests of his pupils. Privileged indeed were the Corpus scholars of his early days, for whom his time was measured not in hours but solely by their capacity to profit by his instruction. His solutions of problems in all branches of mathematics and his methods of exposition were brilliant, and bore full evidence of his powers of clear thinking and of his great originality of mind, and gave hope that he would devote some part of his time to research. But his teaching became an all-absorbing interest, with the result that he published relatively little. He was at his best when talking to two or three pupils at a time in Oxford, and was never quite so happy in London, where it fell to his lot to teach large classes of students. He was quite ruthless with the student who was self-satisfied or uninterested, but spared no pains in helping even the unintelligent, provided he showed a genuine desire for information. He was an excellent head of a mathematical department, inspiring his staff with his keenness, for he took it for granted that all were as conscientious and hard-working as himself. As chairman of a board of examiners he was a tower of strength, and his papers always provided a searching test of the ability of the candidates rather than an opportunity to reproduce a complicated piece of reasoning imperfectly understood.

Jolliffe did not enjoy the leisure of retirement for long, for he was soon recalled to Oxford to help in an emergency in the work of Jesus College, and actually continued in that work until shortly before his death. S. T. SHOVELTON.

Dr. Alexander G. McAdie

WE regret to announce the death, on November 1, 1943, of Dr. Alexander G. McAdie at the age of eighty years. From 1903 until 1913 he was professor of meteorology in the United States Weather Bureau. In 1913 he became Rotch professor and director of the Blue Hill Meteorological Observatory, which post he held until 1931, when he became professor emeritus. In addition to his contributions to the science of meteorology, he was keenly interested in seismology. In spite of the loss by fire of valuable records in the 1906 California earthquake (while Dr. McAdie was working in San Francisco) he prepared, under the auspices of the Smithsonian Institution, a catalogue of earthquakes on the Pacific coast (1897–1906) which has recently been incorporated in a complete catalogue. In the summer of 1906 he called a meeting in San Francisco which led to the formation of the Seismological Society of America. He was its president during 1910–13, and of the Eastern Section during 1929–30.

WE regret to announce the following deaths:

Mr. J. W. Bullerwell, lecturer in physics from 1902 until 1938 at King's (formerly Armstrong) College, Newcastle upon Tyne, and secretary of the University of Durham Schools Examination Board during 1932–42, on March 17, aged seventy.

Dr. Charles B. Davenport, member of the U.S. National Academy of Sciences, the distinguished geneticist who was associated for many years with the Cold Spring Harbor Station of the Carnegie Institution of Washington, on February 18, aged seventy-seven.

Dr. E. C. S. Dickson, senior lecturer in physics in the University of Manchester, on April 8.

Mr. L. V. Lester-Garland, principal of Victoria College, Jersey, during 1896–1911, author of a "Flora of Jersey", on March 23, aged eighty-three.

Mr. E. C. Stuart Baker, C.I.E., O.B.E., a leading authority on Indian ornithology, on April 16, aged seventy-nine.

NEWS and VIEWS

Principalship of the University of Edinburgh: Sir Thomas H. Holland, K.C.S.I., K.C.I.E., F.R.S.

Sir Thomas Holland is retiring from the posts of principal and vice-chancellor of the University of Edinburgh at the end of the present session. In 1929 he succeeded Sir Alfred Ewing at Edinburgh, and the energy which he had shown during the seven years of his rectorship of the Imperial College of Science and Technology in London, and earlier in his war work in India and as director of the Geological Survey there, promised an era of vigorous development in Edinburgh. That promise has been amply fulfilled. He has been instrumental in instituting new degrees (B.Sc. and D.Sc.) in technical chemistry and in mining, and he has negotiated the passing of ordinances by the Privy Council modifying for the better the regulations for degrees in music, forestry, pure science and law. Under his care the teaching power of the University has expanded: nine new chairs have been founded—two in the Faculty of Arts, namely, psychology and geography, five in the Faculty of Divinity, the Edward Clark chair of child life and health in the Faculty of Medicine, and the Reid chair in the Faculty of Music. Although rumours have occasionally been heard of an alleged predilection for scientific interests, it is remarkable that the Faculty of Science is the only one (except law) in which there has been no new foundation during his tenure. Doubtless this apparent omission will be made good in the near future.

The professorial staff of the University of Edinburgh, therefore, increased during the past fifteen years from sixty-one to seventy, and in spite of the fact that about six chairs are vacant owing to war difficulties, this relatively short period has seen a great turn-over in the professoriate, Sir Thomas Holland having installed the present occupants of no fewer than thirty-six chairs. In other ways he has contributed to the development of Edinburgh as an educational centre, notably by the affiliation to the University, in 1933 and 1934, of two important teaching institutions, the Heriot-Watt College and the Royal (Dick) Veterinary College. The teaching and research staff (which has been augmented also by twenty new lectureships) is the most vital part of an educational institution; but buildings are also important, and here, too, great advances have been made. New independent blocks for the Departments of Engineering and Geology and the Institute of Animal Genetics have been erected in the King's Buildings area, which has become a considerable colony of the Faculty of Science, and there a much-appreciated social experiment has been successfully launched in the erection of a Common Room, with refectory, gymnasium, squash and tennis courts, all run by a committee of the students themselves. The creation of a much-needed extension of the medical buildings, already planned, has been unfortunately held up because of the War. It may interest readers, accustomed to standard gibes at the 'close fist' of the Scot, to learn that during Sir Thomas Holland's principalship, private individuals contributed, before the War, more than £500,000 to further the University's aims, and that even during the war years £180,000 has been given by former graduates and friends of the University.

Sir John Fraser, Bart., K.C.V.O.

Sir Thomas Holland will be succeeded in the principalship of the University of Edinburgh by Sir John Fraser, Bart. In Edinburgh the election of the principal is in the hands of the Curators of Patronage, a body consisting of three nominees of the University Court and four nominees of the Town Council of Edinburgh, a reminder of the fact that the "College of Edinburgh" was founded, in 1583, by the Town Council. The Curators' choice of Sir John Fraser will give general satisfaction. He is a medical graduate of Edinburgh, and studied as well in the Universities of Paris and Freiburg; since 1925 he has been regius professor of clinical surgery in the University and will be the first member of the staff to serve as principal since the days of Sir William Turner, who was transferred from the chair of anatomy in 1903. Sir John Fraser has gained fame as a brilliant surgeon, but he has also shown talent as an administrator, and is recognized as a man of generous outlook and keen social sympathies. In the difficult days which lie before the universities, Edinburgh is assured of steady and enlightened guidance, and of a wise balance of effort which will make for progress in all the activities, educational and social, of a great University.

Chair of Geography at Manchester: Prof. H. J. Fleure, F.R.S.

In September Prof. H. J. Fleure will retire from the chair of geography in the University of Manchester. He has held it since 1930, when he vacated the chair of geography and anthropology in the University College of Wales, Aberystwyth. During his tenure of the Manchester chair, Prof. Fleure has built up one of the strongest university schools of geography in Great Britain, and has increased the debt of which all who realize the significance of his subject in higher education were already conscious. He has combined to a remarkable degree unceasing efforts to raise the standard of geographical teaching in every branch of education with the continuous prosecution of active research. As honorary secretary of the Geographical Association and editor of *Geography* for twenty-five years, he has inspired many generations of teachers and greatly increased the facilities for the development of their subject in the schools. At the same time, his wide range of erudition, ripe scholarship and fertility of ideas, as exemplified in the illuminating series called "The Corridors of Time", which he wrote in collaboration with Mr. H. J. E. Peake, have earned him a high place in the field of investigation, which was fittingly recognized a few years ago by his election to the fellowship of the Royal Society. No scholar in Great Britain has done more to justify the claims of human geography, closely linked with both the natural sciences and the humanities but pursuing its own distinct objectives and devising its own technique and methods, to be one of the most illuminating approaches to the study of civilization and its problems.

Mr. Walter Fitzgerald

Mr. Walter Fitzgerald, who succeeds Prof. Fleure in the chair at Manchester, is a graduate of the University of Liverpool. His first appointment was as a lecturer in geography in the Transvaal University College at Pretoria. He returned to

England to become an assistant to the late Mr. W. H. Barker, then reader in geography at Manchester. After the latter's death in 1929, Mr. Fitzgerald was acting head of the Department during the interregnum, and soon after the election of Prof. Fleure to the newly created chair became senior lecturer in geography and has retained that position to the present time. Mr. Fitzgerald has travelled widely and is the author of a standard work on the regional geography of Africa. His views on some fundamental concepts of modern geography have been set forth in a series of three articles in NATURE, the last of which appears in this issue.

State Scientific Research in Great Britain

A STATEMENT of the existing Government organization has now been issued as a White Paper under the title "Scientific Research and Development" (Cmd. 6514. London: H.M. Stationery Office. 2*d*. net), to provide a factual background for the discussion of the part which the Government can play in this field after the War. After describing briefly the constitution and functions of the Development Commission and of the three Committees of the Privy Council for Scientific and Industrial Research, for Medical Research and for Agricultural Research, and the organizations working under them, the statement outlines the existing organization in each of those Government Departments which is faced with special scientific problems peculiar to its own field of activities and administers research and development organizations of its own or has scientific advisers on its staff. A further section of the White Paper describes the provision made by the Government for financial assistance to the universities for fundamental research, and the final section, on co-ordination and control organization, deals with the Scientific Advisory Committee of the War Cabinet and with the responsibilities of the Lord President of the Council in relation to scientific research. Although the statement includes no account of the special war-time activities of the research councils or of the research and development organizations of the Service and Supply Departments (including, for this purpose, the Ministry of Home Security) or of the many establishments working under their direction, it provides a very convenient picture of the structure of the Government organization for research in handy reference form.

Rail and Road Transport in Britain

THE third report from the Select Committee on National Expenditure for the session 1943–44, dealing with rail and road transport in Great Britain, well emphasizes the vital importance of transport in the war effort. The present agreement between the Government and the railway companies, which became operative on January 1, 1941, has given the Government a direct interest in costs of railway operation, and the report notes that receipts have increased, in round figures, by £95,500,000, while expenses have risen by £48,250,000 a year between 1940 and 1942. A close watch over railway operating expenditure is clearly essential from the point of view of national economy. On particular points, the Committee is disturbed at the congestion on the railways, in spite of the relief which the transfer of some traffic to the roads has brought. The congestion has aggravated an already serious coal situation, because filled wagons at colliery sidings have often not been movable, and the first recommendation is that the call-up of railway workers should cease, and that a steady influx of labour should be directed to the railways. Zoning has effected appreciable economies in railway transport. As regards passenger traffic, the Committee recommends that immediate consideration be given to the formulation of plans for the compulsory staggering of holidays. With regard to road transport, it is recommended that the Ministry of War Transport should immediately and closely re-examine the present freight charges and adjust them where necessary. The report also considers the Road Haulage Organisation, and the criticism of the scheme from the industry and the Ministry's reply. There is much evidence of extravagant use of vehicles and capacity, and the report finally recommends that a close scrutiny be made of the work of divisional and area haulage officers, and more particularly that of unit controllers, with the view of more economical use being made of lorries and their carrying capacity.

British Union Catalogue of Periodicals

AT the Association of Special Libraries and Information Bureaux Conference held in November 1942, following a paper presented by Mr. Theodore Besterman "On a Proposed Union Catalogue of Periodicals", the Association was requested to consider the possibility of publishing a union catalogue of British and foreign periodical publications on all subjects and of all dates, the location of which is traced in a library in the British Isles. A committee under the chairmanship of Dr. Luxmoore Newcombe, librarian of the National Central Library, and including members of the Library Association, the British Museum staff, the Joint Standing Committee on Library Co-operation and the Science Museum Library, satisfied itself that the project was practicable, and that the resulting Catalogue would prove an invaluable bibliographical tool. It was estimated that the compilation of the preliminary check-list, prepared from existing union and other lists and catalogues, would take about five years and that this check-list, in itself, would be of the utmost value. Moreover, it was clear that the planning of post-war rehabilitation of British library services must be based on an assessment of their present holdings, and for this alone the check-list would provide most useful help.

The project was submitted to the trustees of the Rockefeller Foundation, who have agreed to appropriate, for a period of five years beginning February 1, 1944, up to £14,000 to the Association of Special Libraries and Information Bureaux for the British Union Catalogue of Periodicals. Although the work will remain under the financial and general direction of the Association, the actual operative control of the production of the Catalogue will be in the hands of an executive council representative of the leading British library and bibliographical interests. The first meeting of this Council was held on March 28, when Mr. Theodore Besterman was appointed editor. Work on the compilation of the check-list will begin at once.

Australian Forestry in War-time

WITH the Dominion of Australia in the 'front line' and the necessity to conserve shipping space, timber has proved more important to Australia in this War than in that of 1914–18 (*Australian Forestry*, 7; 1943. Pilpel and Co., Perth, Western Australia). When a country's industrial effort expands, its timber demands expand also, as already exemplified in the

article "The Forest as a Factory" (NATURE, February 26, p. 243). In spite of the handicaps of loss of man-power and shortages of plant and equipment, the saw-milling industry of Australia rose to the emergency and increased production to a peak which fulfilled all demands at the time. Latterly, however, there has been a serious decline owing to lack of labour, trucks, tractors, spare parts and so forth—rather like the position of farming and its mechanization, in some parts at least, of Britain. It is not surprising to read that some States in Australia which were previously exporters are now importers, and that the timber control authorities have had to reorientate the flow and usage of timber. Civilian demands are treated very much as in Great Britain, and plywood is said to be already unprocurable. It is difficult to foresee what will be the ultimate demands upon the forests of the country, but it appears certain that a careful consideration of a future forest policy for the continent as a whole will be essential, if the country is not to be faced with the twin evils of increasing aridity and depreciation of water supplies, the usual aftermath of excessive and hurried forest fellings, no matter how justified these may be at the present time.

That the possible post-war needs are realized is indicated by the following quotation: "Timber, the raw material for such a widespread national industry as sawmilling, as well as paper and pulpwood manufacture, plywood and wall board fabrication, etc., can only be obtained in continuing supply under a well-planned and uninterrupted forest policy". The value of a long-term planting scheme is demonstrated by the exotic pine forests in the south-east of South Australia, from which 40,000,000 super feet of soft-wood are now being cut annually where originally there was only inferior hardwood forests of very limited extent. "The establishment of plantations and the successful regeneration of heavily-cut forests will require the skill and experience of trained foresters in greater numbers than are available to-day. For this reason alone there is a necessity to initiate the immediate training and education of men who can be called upon later for this work. State authorities would help the post-war problem considerably by giving urgent attention to this most important question. In some cases this will involve, as in the case of other professional training, a temporary loss of services to the armed Forces, which, however, must themselves benefit from this very training." Both New Zealand and Australia have recognized the wisdom of this latter step; the Ministry of Labour and National Service in Great Britain has so far found it difficult to appreciate this aspect of the problem.

The Planetary Companion of 61 Cygni

DR. ROBERT AITKEN has given a short account of the new companion to 61 Cygni, which has aroused considerable interest because of its planetary nature (*Astro. Soc. Pacific*, Leaf. 177; 1943). In 1914, Hertzsprung perfected a photographic method for measuring the motion in double stars, and this method gave results of much higher accuracy than those obtained by other means. It is considered that the photographic measurements made by this method by Hertzsprung with the long-focus telescopes at Potsdam and at the Lick Observatory, and by Strand at the Sproul Observatory, are the most accurate double-star measures that have been made. When Strand plotted the measures of the two bright components of 61 Cygni, from 1914 on, he found that the curve of their relative motion was not a perfectly smooth ellipse, but a wavy line, and this wave motion could even be traced backwards from 1914 by the use of plates taken by Lewis M. Rutherford by the old wet-plate process.

There is now no doubt about the existence of the third small body, which revolves with one of the bright stars in a period of 4·9 years. The mass of 61 Cygni *C*, the name given to this small body, is about ten times that of Jupiter, and it is very doubtful whether it is permissible to extrapolate the stellar relationships between mass, temperature, luminosity and density, to such a relatively small body, which cannot be considered a normal star. Prof. H. N. Russell states (*Astro. Soc. Pacific*, Leaf. 170; April 1943) that we are dealing with a borderline body, and discusses a number of problems that arise in connexion with such a unique discovery. There is no reason why many other similar bodies should not exist, but those that are far removed from us would be difficult to discover.

Shasta Dam

THE possible effect of earthquakes has been taken into account in the building of the Shasta Dam (*Earthquake Notes*, Eastern Section, Seismological Society of America, 15, Nos. 1 and 2, Sept. 1943, p. 4). An analysis was first made, according to Kenneth B. Keener, of the conditions existing both when the reservoir is full and when it is empty, each with and without earthquake effects, and in view of this analysis certain assumptions were made. These assumptions were then taken into account when designing the structure of the dam. The assumptions were: (1) the uplift pressure is not affected by the earthquake shock; (2) the horizontal and vertical components of an assumed earthquake shock have an acceleration equal to one tenth gravity, and a vibration period of one second; (3) the horizontal component has a direction of vibration normal to the axis of the dam.

Bibliography of Seismology

THE Bibliography of Seismology, published at the Dominion Observatory at Ottawa and compiled by Ernest A. Hodgson (13, No. 13, items 5440–5563. January to June 1943), has just been received. It contains items of interest to seismologists from almost pure geology, physics, chemistry and applied mathematics through pure seismology to notices of seismic patents for prospecting. Several items have already been noticed in the columns of NATURE. Interesting applications of seismology occur in items 5,480 and 5,500. The former concerns "Instruments for Measuring Vibrations in Grand Coulee Dam" and refers to *Engineering News Record*, 129, 64 (New York, Dec. 31, 1942). The latter, by Ernest A. Hodgson, refers to "Rockburst Research in Lake Shore Mines" and is to be found in *Miner and Mine*, 1, No. 1, 4–5, Kirkland Lake, March 1943. Item 5562 refers to a most careful piece of work by Harry O. Wood, "Earthquakes and Disturbances to Leveling in the Imperial Valley", and is taken from *Bulletin of the Seismological Society of America*, 32, No. 4, 257–268 (Berkeley, Oct. 1942). The United States Coast and Geodetic Survey surveyed the area by precise levelling in 1926–27, 1928 and 1931, and sent a field investigation unit to the Imperial Valley, California, in 1930, after the earthquakes of February 25 and March 1, 1930. The author's opinion of the probable cause of the change in levels between 1927–28

and 1931 is the slumping and compaction of the water-charged ground near the surface, with local buckling, due to vigorous shaking in 1930. The gross changes which occurred in 1940 were of a wholly different order. The occurrence of the 1940 earthquake with disclosure of a surface fault offset necessitates review and reconsideration, and may, according to H. O. Wood, point to activity along the fault zone in 1930, though the other opinion may be upheld. The author emphasizes the necessity for frequently repeated precise surveys.

Soil Erosion in New Zealand

In an article entitled "Contrasting Regional Morphology of Soil Erosion in New Zealand" (*Geog. Rev.*, January), Mr. K. B. Cumberland directs attention to the seriousness and rapidity of soil erosion in New Zealand, not merely in the wet region of the North Island but also in certain comparatively dry areas in the South Island. In the south-west of the North Island, the horizontally bedded mudstones, sandstones, marls, etc., were continuously forested until some fifty years ago, when intensive pastoral invasion began. Some forest still remains, but over-grazing has tended to decrease vegetation and allow gullying and soil flow to take place on an alarmingly destructive scale. Some of the area is reverting to bush, but without active reafforestation the harm cannot be checked. In the South Island the drier central Otago basin originally had a steppe covering. Here the destructive features of occupancy have been burning, over-grazing and rabbits. The removal of close plant cover has exposed the surface soil to the action of wind, frost and moving water, and its removal is facilitated by the nature of the rock, mica schist, which readily crumbles. Thus much land is being wasted. Lastly, the sluicing and dredging of gold mining is making havoc in places. These are but two examples of a menace that appears to be as widespread in New Zealand as in many other lands.

Guthrie Lecture of the Physical Society

The twenty-eighth Guthrie Lecture of the Physical Society is to be delivered by Dr. Joel H. Hildebrand, professor of physical chemistry in the University of California, at the Royal Institution, London, at 5 p.m. on April 26, and at the Clarendon Laboratory, Oxford, at 2.30 p.m. on April 29. Prof. Hildebrand's presence in England enables the Society to add his name to the select list of Americans who have delivered the Guthrie Lecture: R. W. Wood (1914), A. A. Michelson (1921), P. W. Bridgman (1929) and A. H. Compton (1935). He is known for his long record of research on solubility and solutions, and will take "The Liquid State" as the subject of his lecture.

Institute of Physics: Scottish Branch

Physicists employed in industry in Scotland have for some time felt the need of local opportunities for the interchange of knowledge and experience of applied physics. At their request the Board of the Institute of Physics has therefore authorized the formation of a Scottish Branch of the Institute, which is to be centred in Glasgow. The inaugural meeting of the Branch will take place on April 22 at 2.30 p.m. in the Chemistry Buildings of the University of Glasgow. Mr. E. R. Davies, a vice-president of the Institute and director of research at Messrs. Kodak, Ltd., will deliver an illustrated lecture on "High-Speed Photography, and its Applications in Science and Industry". Admission is free and without ticket. Further particulars of the Branch may be obtained from the acting honorary secretary, Dr. R. S. Silver, c/o Messrs. G. and J. Weir, Ltd., Cathcart, Glasgow, S.4.

Part-time Day Advanced Mining Scholarships

The Miners' Welfare Commission invites applications for a limited number of part-time day advanced mining scholarships tenable, as from September next, at approved institutions providing day classes in advanced mining instruction. Candidates for these scholarships must be wage-earning coal mine-workers, have been so employed for not less than eighteen months, at least seventeen years of age on September 1, 1944, and have satisfactorily completed an approved part-time senior mining course. Each scholarship will be awarded in the first instance for one year but will be renewable up to a total period of four years. The awards consist of a sum not exceeding £30 to cover fees, books, instruments and travelling expenses and to compensate or assist the student for loss of wages in attending the course one day weekly (or two half-days). The scholarships will be awarded on the results of a competitive examination. Application forms can be obtained from the principals of the chief mining schools.

Announcements

The following were elected officers of the Royal Astronomical Society at the annual general meeting: *President:* Prof. E. A. Milne; *Treasurer:* Mr. J. H. Reynolds; *Secretaries:* Dr. H. R. Hulme and Mr. D. H. Sadler; *Foreign Secretary:* Sir Arthur Eddington.

Mr. R. N. Johnson, formerly research chemist with Messrs. Tootal Broadhurst Lee Co., Ltd., has been appointed administrative officer to the British Leather Manufacturers' Research Association.

The following appointments have been made in the Colonial Forest Service: R. F. Clarke Butler-Cole, assistant conservator of forests, Nigeria, to be senior assistant conservator of forests, Nigeria; D. McIntosh, assistant conservator of forests, Nigeria, to be senior assistant conservator of forests, Nigeria.

The British Mycological Society is making a collection of surplus reprints and pamphlets on mycology and plant diseases for distribution after the War to libraries and centres of research at home and abroad which have suffered loss or damage. Authors are invited to send reprints of their own published work and any other reprints or pamphlets which they can spare to Mr. G. C. Ainsworth, secretary of the British Mycological Society, Imperial Mycological Institute, Ferry Lane, Kew, Surrey.

The twenty-fifth anniversary of the formation of the Wireless Section of the Institution of Electrical Engineers will be marked by a commemoration meeting and dinner to be held on May 3. At the commemoration meeting short addresses will be delivered, comprising a review of wireless progress, by past chairmen of the Section, there will be a short gramophone recital dealing with important events in wireless development and, if time permits, films will be shown of Sir Ambrose Fleming and Sir Oliver Lodge. An exhibition of apparatus of historical interest, kindly loaned to the Institution by the British Broadcasting Corporation, Marconi's Wireless Telegraph Co., and others, is being arranged.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Action of Inert Dusts on Insects

Kitchener, Alexander and Briscoe[1,2] have proved conclusively that certain chemically inert dusts kill insects by causing them to dry up. The effective dusts increase evaporation through the cuticle—possibly, it is suggested, because the "epicuticle fat film" is preferentially attracted by the crystalline forces at the surface of the solid particle of dust, thus interrupting the continuity of the film over submicroscopic areas. These authors found that the effect was produced only on living insects.

From observations, mainly on the bug Rhodnius but confirmed in other insects, it appears that an important factor in the action of the dusts is the simple abrasion of a film of wax (probably associated with protein) which lies outside the epicuticle. If alumina dust is applied generously to all parts of a living Rhodnius nymph suspended in mid-air, evaporation is not increased (see accompanying table). But if the insect runs on filter paper lightly treated with the dust it is completely desiccated within twenty-four hours. As the Rhodnius nymph walks, its abdomen touches the ground. But if this is prevented by placing a little mound of wax on the bearing surface, although the insect soon becomes covered with the dust, it will survive for many days, such increase in evaporation as occurs being due to the chance abrasion of other parts and to the dust getting between the moving articular surfaces. A smaller increase in evaporation results if the insect runs on emery cloth (see table).

Treatment of Rhodnius 5th stage nymphs (recently fed)	Average loss of weight per cent in 24 hours in dry air at 30° C.
Running on clean filter paper	2·2
Suspended in air and heavily dusted with alumina	1·9
Running on emery cloth No. 0	7·8
Running on filter paper lightly dusted with powdered quartz (0·5–1 μ)	17·8
ditto, with a mound of wax on the main bearing surface	5·2
Running on filter paper lightly dusted with alumina	43·5
ditto, with a mound of wax on the main bearing surface	7·6

It is well known that the outer layers of the insect cuticle contain polyphenols[3,4] which will reduce ammoniacal silver hydroxide. But if the insect is immersed in the silver solution no blackening occurs. There is clearly some protective layer outside the epicuticle. If a Rhodnius nymph which has been running on dusted filter paper or on emery cloth is so treated, however, all the prominent portions of the cuticle, where this has been in contact with the surface, are stained deep brown: the protective film has been abraded (Figs. 1, 2). Before treatment with silver the cuticle shows no change that is detectable with the microscope; there is no visible injury to what is commonly referred to as the epicuticle.

If the insect is kept in a moist atmosphere after rubbing lightly with the dust, its impermeability to water is largely restored; and after some days the rubbed area is covered with a waxy bloom. This recovery does not take place in the insect treated

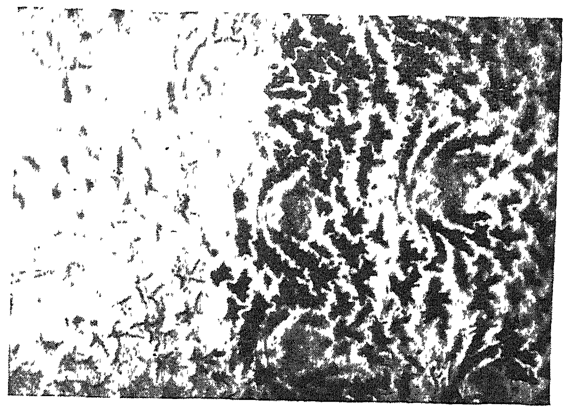

Fig. 1. Cuticle of Rhodnius treated with ammoniacal silver. Reduction is limited to the crests of the epicuticular folds of the area to the right which has been rubbed by the dust.

with cyanide. It is far less complete if the dust is allowed to remain on the cuticle; showing that, as suggested by Kitchener *et al.*[1], adsorption of the wax is important, at least while it is being secreted. The wax appears to be secreted, not by dermal glands, but through the substance of the cuticle by the epidermal cells. This raises some interesting physical problems.

These observations have a bearing on the passage of insecticides through the cuticle. It has often been observed that certain dusts favour the action of insecticides[5]. Perhaps they do so in virtue of their

Fig. 2. Puparium of Calliphora lightly rubbed with alumina showing the reduction of silver over the prominent folds.

abrasive or adsorptive properties. If 2 per cent nicotine is applied in a capsule to a standard area on the back of a Rhodnius nymph[6], the insect is slightly affected in six hours, badly affected though not collapsed in twenty-four hours. If the back is first lightly rubbed with alumina dust, complete collapse occurs within twenty minutes. If powdered rotenone (Stafford Allen 90 per cent) is used, the normal insect remains alive for weeks; the insect treated with the dust shows weakness in eight hours and is dead in less than twenty-four hours. It may therefore be desirable deliberately to incorporate abrasive material as an adjuvant in insecticidal dusts.

This work forms part of a comparative study of the physiological properties of the waxes in the

cuticle of different insects which will be published in full elsewhere. A parallel study of the isolated waxes is being made in this laboratory by Mr. J. W. L. Beament.

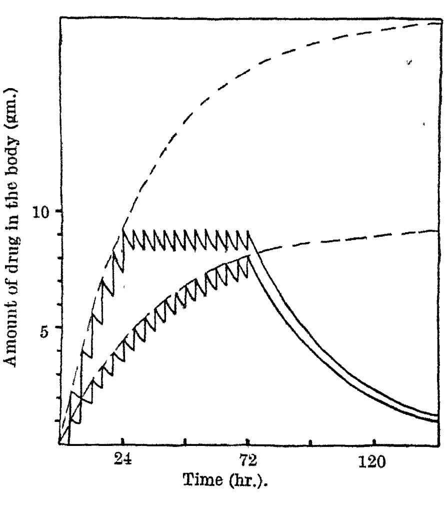
Repeated Doses of Drugs

THE following calculations, which deal with the theory of the accumulation of drugs in the body, involve two assumptions which are known to be justifiable in certain cases. The disappearance of the drug from the body is assumed exponential, and the time taken for absorption and distribution is neglected.

Let a series of equal doses (d) be given at equal intervals of time (t') in such a way that no dose is given at zero time and the first dose is given at time t'. Let the concentration produced in the body, or in the plasma, by one dose be d. Let the total concentration at time t be D, and let the drug disappear according to the formula $\frac{dD}{dt} = -kD$, or $D = D_0 e^{-kt}$. At the end of the second interval of time, $D = de^{-kt'}$, or dp, where $p = e^{-kt'}$. Immediately after the second dose, $D = d(1 + p)$, and immediately after the n^{th} dose, $D_n = d(1 + p + p^2 + \ldots + p^{n-1})$. The expression for the sum of this series gives $D_\infty = d/(1 - p)$. This expression can also be deduced from the fact that, when the curve ceases to rise, the effect of each dose (d) must exactly replace the amount disappearing between doses $[D_\infty(1 - p)]$. Simple algebra gives the result

$$D_n/D_\infty = 1 - p^n = 1 - e^{-knt'} = 1 - e^{-kt}.$$

The maxima of the curve of accumulation therefore lie on a curve which is identical with the curve of the disappearance, but inverted. This is true whatever the dose and whatever the dose interval. The curve through the minima lies below the curve through the maxima at a constant distance corresponding to the size of a single dose. It is thus possible to predict the accumulation of a drug from a knowledge of its disappearance.



Curves of accumulation. Time for half-clearance = 24 hours; $1/k$ = 34·6 hours; t' = 4 hours; p = 0·891. *Lower curve*—d = 1 gm.; D_∞ = 9·2 gm. *Upper curve*—first 6 doses = 2 gm.; D_∞ = 18·4 gm.

The time taken for a drug to accumulate in the body is often too slow for therapeutic requirements and is diminished by giving large doses in the early stages of treatment. It may be calculated that, if the dose, or the rate of dosing, is doubled, the time taken for the curve through the maxima to reach 90 per cent of its final value on single doses is reduced to about 26 per cent of the time which would be taken if single doses were used throughout. If the dose is quadrupled, the time is reduced to about 12 per cent, provided that the approximations mentioned above are still valid.

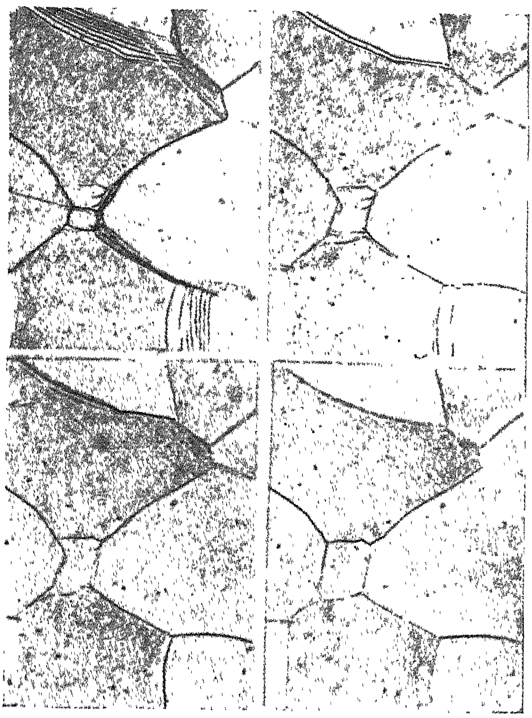
Thermal Fatigue of Metals

WHEN small steel-backed bearings of tin- and lead-base alloys were repeatedly heated and cooled over the range 30°–150° C., marked cracking occurred throughout the tin-base alloy, but not in the lead-base alloy. Continuation of the cyclic process led ultimately to the disruption of the tin-base alloy. Since specimens of similar alloys *unattached* to a steel shell were found to behave in the same manner, it was thought that the metals forming the bases of the alloys were responsible for the difference in behaviour. For this reason, lead (99·99 per cent) and tin (99·9 per cent) were examined under the same conditions, the investigation being later extended to cadmium (99·97 per cent), zinc (99·97 per cent) and tellurium (B.D.H. Purity).

The specimens of lead, tin, cadmium and zinc were in the annealed state and all but lead were electrolytically polished. The lead specimens were prepared by careful polishing followed by etching with the usual acetic acid – hydrogen peroxide reagent. These methods were adopted to obtain surfaces for metallographic examination which were free from deformation. The specimens were then alternately heated and cooled over the range 30°–150° C. for a number of cycles. In the case of tin, cadmium and zinc, this treatment produced definite signs of plastic deformation, indicated in some cases by twinning and in others by slip lines. Photomicrographs illustrating the effect for cadmium are reproduced herewith. Close examination of lead specimens treated in the same manner failed to reveal any evidence of plastic deformation.

In the majority of cases, plastic deformation was observed even after one cycle, but it was limited to a few grains only. As the number of cycles was increased, signs of plastic deformation appeared in more grains and became more pronounced in individual grains until finally most grains were affected.



Thermal fatigue of pure cadmium (× 300) after heating from 30° to 150° C. and cooling: (a) as polished; (b) after 1 cycle; (c) after 2 cycles; (d) after 15 cycles.

Variation in the duration of the cycle and the rates of heating and cooling made no perceptible difference to the magnitude of the effect. Variations in the length of the cycle from 7 minutes to 6 hours, that is, a ratio 1 : 50, did not alter to any great extent the degree of deformation obtained.

In order to investigate the effect of temperature, specimens of cadmium were observed under the microscope while heating and cooling. It was found that the lines indicating deformation appeared mainly on heating; thus apparently the heating portion of the cycle was responsible for the greater part of the deformation. It was clear that plastic deformation occurred even after small temperature changes, but became much more pronounced with further rise in temperature, until at 150° C. the effect was very marked.

It was noted that the magnitude of the effect varied with the metals used. Plastic deformation occurred more readily in cadmium than in tin, while the effect in the case of zinc was at least as pronounced as in cadmium. When cadmium was cast on glass plates, examination of the mirror-like undersurfaces of the globules formed revealed distinct slip and twinning. Tellurium behaved somewhat differently because of its brittle nature. On the undersurfaces of tellurium globules cast on glass or mica, slip lines and even cracks were seen. After a number of cycles, some of the cracks extended.

Examination of cadmium specimens after each cycle showed that considerable movement of grain boundaries occurred. This migration was also very evident in the case of tin. It seems to be associated with the plastic deformation in the grains. Some grain boundaries moved more than others, while some were quite stationary. Many instances were detected where a grain boundary impression was formed after each cycle, with the result that, finally, a network of boundaries was formed. Such a boundary migration was detected in a tin-base alloy by Carpenter and Elam[1], who used the phenomenon to trace the growth of crystals on annealing after deformation. Rosenhain and Ewen[2] found that when mechanically polished silver was annealed, twins were formed. This twinning was apparently due to mechanical deformation by this type of polishing. It is evident that this phenomenon is different from that described above. Furthermore, these authors did not find a similar effect with zinc.

The name 'thermal fatigue' is suggested for the effect because of its analogy with that of repeated *external* stresses on metals. In both cases, the specimen is subjected to cycles of stress which produce plastic deformation of the crystals. If the stress is larger than a certain limit, progressive damage is done, and finally failure occurs. The cause of the stresses in the specimens of *non-cubic* metals subjected to thermal cycles seems to be the anisotropy of thermal expansion. This explanation is supported by the fact that no deformation of this type has been detected in the cubic metal lead, whereas it has been found in tin, cadmium and zinc, which are non-cubic metals possessing marked anisotropy of thermal expansion[3]. The theory is further supported by the observation that the rates of heating and cooling of the specimens seemed to be of little significance. An approximate calculation shows that the stresses developed in the crystals are proportional to the temperature change, the difference between the maximum and minimum coefficients of thermal expansion of the crystal, and an average value of Young's modulus[4]. The ratio of the stress to the critical shear stress of the crystal may be used to indicate the likelihood of plastic deformation, although this is only a first approximation. The numerical values indicate that the metals lie in the order, tin, cadmium, zinc, with respect to the increasing probability of occurrence of plastic deformation for a given temperature range. The experiments seem to be in agreement with this classification.

It appears, therefore, that metals which possess a high degree of anisotropy of thermal expansion cannot be obtained in a strain-free condition at room temperature by casting or annealing. It is possible that deposition from the gaseous state might give strain-free crystals. Apart from its theoretical interest, the effect has implications in the field of bearings where tin-base and cadmium-base alloys are in common use. Many such bearings are subject to frequent temperature changes of the order of 100° C., and the phenomenon described might well contribute to their ultimate failure in service.

We wish to express our thanks to Dr. F. P. Bowden for his interest and encouragement in the work.

Bacteriological Diagnosis of Gas Gangrene due to *Clostridium oedematiens*

IN gas gangrene infections it is important to determine the infecting organism as quickly as possible, but hitherto there has been no satisfactory method available for the rapid recognition of *Cl. œdematiens*. By means of the cultural reaction described below, it is hoped that it will usually be possible to make a provisional diagnosis in less than twenty-four hours. With heavily sown or overgrown plates, in which the reaction may be doubtful, it may be necessary to subculture without delay from a suspected colony to a fresh plate.

The medium employed is a modified Weinberg's V.F.[1] agar (2·25 per cent) to which 10 per cent defibrinated sheeps' blood and 10 per cent egg yolk suspension is added. The egg yolk suspension consists of equal parts of normal saline and egg yolk freshly removed from an egg aseptically. In surface cultures on plates of this medium, colonies of *Cl. œdematiens* attain a diameter of 0·8–1·5 mm. after 16 hours incubation anaerobically. Colonies of *Cl. œdematiens* type *A* are surrounded by a hæmolytic zone outside which is a dark red 'reduction' zone. Covering the colonies and the hæmolytic zone is an opaque film with a mother-of-pearl lustre. All available species of Clostridia and a number of common aerobes have been tested, but none of them produces both the pearly layer and the reduction zone together, although some species show one or the other feature separately.

Although we have had the opportunity to test this method of diagnosis on actual clinical material in only five cases to date, our experience with these cases and with artificially mixed cultures suggests that it will be possible to detect *Cl. œdematiens* type *A* in material from lesions in which various other organisms are present. Swarming is avoided by opening and drying the plates for approximately five hours in the incubator before inoculation.

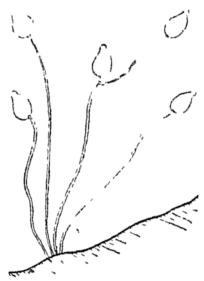
Species of Phytophthora as Water Moulds

AT the last meeting of the British Mycological Society I directed attention to the fact that (although omitted from published lists of water moulds), parasitic species of Phytophthora may live for long periods of time as water moulds. Masquerading thus as saprophytes, they may be dispersed in water and carried to fields where they may become parasitic upon crops. I suggested that with the co-operation of fellow mycologists, naturalists, microscopists and 'pond-dippers', it should be possible to determine the distribution of these species in the streams, ponds, ditches, even bird-baths, of Britain; and I appealed for helpers. I should be grateful for space in NATURE for the following instructions on how to find, and to send to me, anything that looks like a possible member of the Pythiaceæ, collected in this way.

Method. Collect from streams, ponds, etc., half-decayed fruits, twigs, stems of water weeds which are bearing a straggling, greyish mycelium probably in a bacterial slime. It may be necessary first to put the fruits, etc., into the water, that is, to 'set bait', and this is best done in some container (within which the bait will not be reached and eaten by goldfish, snails, etc.).



Bait. (1) Fruits. hips, haws, windfall apples, small tomatoes and other berries. (2) Seeds, for example, hemp. (3) Thin twigs and leaf stalks, cut into short lengths.

Container. (1) Galvanized tin with holes punctured in the top and bottom. (2) Glass jar with coarse muslin stretched over the mouth.

Treatment. Allow from a few days to a month or more to pass before gathering bait (leaves and soft fruits are attacked by fungi more quickly than are twigs and seeds). Wash the 'bait' well in tapwater, and keep it in the dark. It is possible that sporangia may not appear until after the water has been changed.

Identification. Hyphæ: coenocytic (no cross walls), of various widths, branched. Sporangia: ovoid with papilla, borne at the end of a slender hypha.

Transport. Drain the material collected and wrap in damp paper; enclose it in a tin and post it to me with the following particulars (and, if possible, drawings): (1) nature of substratum or 'bait'; (2) nature of water, (*a*) flowing or stagnant, (*b*) acid (alkaline or neutral), (*c*) depth; (3) date of collection, and, if bait set, date of setting bait; (4) any further treatment.

Material will be most appreciated this year in May, June, September, October, November. I will refund postage and, if asked, return the tin. I shall gratefully acknowledge, in any subsequent report, all help given.

Variation in the Nitrogen-fixing Property of *Rhizobium trifolii*

WHILE testing a number of strains of *Rhizobium trifolii*, two cases have occurred (cultures 61 and 91, isolated from *Trifolium tomentosum* L. and *Trifolium glomeratum* L. respectively) in which a culture, from a single colony developed from a single nodule, has shown at the time of its first testing on white clover (*T. repens* L.) the presence of definite 'sub-strains' with distinctly different nitrogen-fixing ability. Culture 91 showed the same behaviour when tested against *T. glomeratum*. In each case, while some plants were scarcely better than those of the uninoculated control, other plants in the same pot were very much better. The former showed the usual characteristics associated with inefficiency, namely, early yellowing of cotyledons, poor yellow growth and the presence of many small nodules. The healthier plants carried typically large effective nodules, although other smaller nodules, similar to those on the poorly grown plants, also occurred.

Re-isolations were made from weak and vigorous plants and from small and large nodules. Re-isolates from both 61 and 91, when tested serologically against sera of studied antibody constitution[1], gave the same reactions as the original culture. Antibody absorption tests confirmed this result. This serological identity of the 'sub-strains' argues conclusively against the possibility of contamination, particularly in the case of 91, which represents an uncommon serological form which has been encountered on only one other occasion in about a hundred isolations from a wide range of plants. Re-isolates from 91 were tested for efficiency with cluster clover (*T. glomeratum* L.) grown on Crone's agar in large tubes plugged with cotton wool, observing the usual precautions. Results are set out below:

Re-isolate	Effectiveness	
Pot 7, LL	Effective	LL: large nodule, large plant.
,, SL	Ineffective	
,, SS	Ineffective	SL: small nodule, large plant.
Pot 12, LL	Effective	
,, SL	Ineffective	SS: small nodule, small plant.
,, SS	Effective	

There seem to be three possibilities: (1) The original nodules carried 'sub-strains' which belong to the same fundamental strain, as judged on serological evidence, but have at least two distinct levels of nitrogen-fixing ability (always in respect of a particular host). (2) A variation occurred in culture within a short time (several months) and in the course of relatively few sub-cultures, following isolation. (3) Exposure of the organism to the test plant caused an immediate variation. It is felt that the first of these alternatives is the most likely explanation. Experience with Pot 12,88 might be contributory evidence. The selection of an effective culture from what seemed to be an inefficient nodule might have been due to the nodule carrying organisms of different nitrogen-fixing ability.

The apparent lability of characteristics in the organism which affect its ability to form an effective association with a particular host contrasts with the serological stability revealed in previously reported studies[1,2,3] and agrees with the experience of other workers (as, for example, Allen and Baldwin[4]). However, in respect of the plant passage experiments of the last-named workers, it is suggested that the experience reported in this note raises the possibility that the change in efficiency attributed by them to plant passage might have resulted from a selection of already existing variants rather than from variation induced by repeated exposure to the host plant. The results also emphasize what is continually being found in this laboratory, namely, the lack of any apparent relationship between serological constitution (as revealed by present techniques) and the factors responsible for efficient association with a host plant. Serological methods, however, have considerable value in the designation of strains and provide a convenient basis for reference in connexion with several aspects of root-nodule investigations.

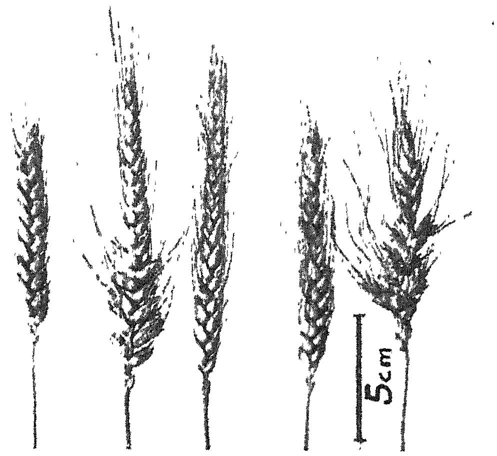
Branched Heads in Wheat and Wheat Hybrids

The accompanying photograph shows the parents and *F*1 progeny of a cross between a normal bearded bread wheat (*Triticum vulgare*, Host, $2n = 42$) and a branched or 'miracle' headed rivet wheat (*T. turgidum*, L., $2n = 28$). *A* is a head from the pure line used as the female and *B* one from that used as the male, both from plants grown out of doors. Half the hybrid grains were started in Petri dishes on December 30, 1942, and the seedlings transferred about a week later to a greenhouse heated just sufficiently to keep out frosts. The remaining half was treated in the same way about the first week in the following February (the exact date is unfortunately lost).



A *C* *D* *E* *B*

When the *F*1 plants had headed it was seen that all those first sown bore branched heads, one of which is shown at *C*, while all those sown later bore completely unbranched heads (*D*) exactly like the female line in this respect. When the plants tillered, these heads were unbranched, both in the case of the first sown plants (*E*) as well as in the second group.

The branched-headed character is caused by some of the lower buds, which normally only develop into single spikelets, growing out vigorously and so producing small heads of their own. This character is usually stated to behave as a simple recessive to the normal unbranched condition (Percival[1] quoting Tschermak), but apparently this is only part of the story. It would seem that the expression of this allele is greatly influenced by the day-length and perhaps the temperature under which the plants are growing. The variation described above correlates well with the observations of Hurd-Karrer[2] on the growth of normal winter and spring bread wheats when kept under constant low (12° C.) and high (21° C.) temperatures and short (8 hr.) and long (17 hr.) days. She found that at both low and high temperatures, short days produced long heads, the lengthening being most pronounced at the low temperature and mainly due to an increase in the distances between the lowermost spikelets. Under conditions of short days and low temperatures a secondary head was sometimes produced from the axil of the topmost leaf, and in Turkey, the winter wheat used, the main heads were often branched giving miracle-headed bread wheats.

Long days produced very short heads. In the winter wheat used, long days and the higher temperature often led to a failure to produce heads at all but resulted in the development of an elongated shoot with multiple vegetative branching at the nodes—a state similar to that commonly found in England in Agrostis, Festuca and Holcus during the autumn and called by Arber[3] the "pompon or mop habit".

Temperature	Short → Long Day-length	
High ↑	Long heads (2)	No heads + pompon habit or Short heads (4)
Low	Long heads or Branched heads (1)	Short heads (3)

If the above table represents the general interactions of day-length and temperature on wheat, then in homozygous branched-headed *T. turgidum (bh bh)* the area of the rectangle 1 is comparatively large so that normal sowing will fall within these limits and miracle heads be produced. In the heterozygotes, *Bh bh*, resulting from the cross normal *T. vulgare (Bh Bh)* × branched-headed *T. turgidum (bh bh)* the rectangle is smaller, so that in the greenhouse, at any rate, only early sowing will give miracle heads; tiller heads from early-sown plants and main and tiller heads of late-sown plants will be developing under conditions outside this rectangle. The area is smaller still for normal winter bread wheat, *T. vulgare (Bh Bh)*, but as Hurd-Karrer has shown, short days and low temperatures will still give miracle heads. Presumably still shorter days with or without lower temperatures would give branched heads even in normal spring bread wheat.

There are limits outside which homozygous branched-headed *T. turgidum* itself will not produce miracle heads. With the late-spring sowing usually necessary for outdoor material in Leeds, in some years the pure lines show very little branching: one year, in fact, the only trace was the presence of occasional double spikelets at the base of the heads. Presumably this is due to the relatively early onset of long days in this latitude. With spring sowing, at any rate, it has never been possible to produce here the magnificent branched heads figured in the literature. The average reached is about that shown at B, although the parent head of this line (generously given by Mr. A. E. Watkins from his Cambridge-grown material) was considerably more branched.

It would seem that the branched-headed factor operates by altering the branched/normal-headed threshold and so can be made to behave as either a dominant or a recessive at will.

Simple Sensitive Flames

IN his letter which appeared in NATURE on March 25, Dr. Sutherland sets out to show, if I understand him aright, that a sensitive flame possesses certain very sharply defined frequencies of response, independent of the parameters of the jet, which is certainly "surprising and difficult to explain", especially with this very heavily damped system. What exactly these frequencies are I am unable to decide from his diagram, since I note that two of the three sharply defined maxima of his lower diagram agree exactly with sharply defined minima in the upper diagram. Perhaps this is significant?

In the paper which he quotes[1] I showed, working with a liquid-into-liquid jet, which is much better adapted for quantitative work than a flame, that these very sharp responses undoubtedly existed, but that many of the frequencies could be traced to resonances of the supporting structure, since they could be easily varied by loading it. I also brought forward evidence that the others were due to resonances of the room. Further, if the disturbance of the jet was produced by a small local vibrator, a centimetre or so from the orifice, which was too feeble to act appreciably on the framework or on the room, there was the same type of general response as was produced by the ordinary sound source but no selective response at all. This appeared to me conclusive.

If Dr. Sutherland should feel that the matter really needs "a critical comparative examination" of what he calls "the two claims" by an authority of weight, I venture to suggest that he start his investigation by repeating my experiment of vibrating in still air the orifice from which the flame issues. If he gets sharply defined response at the same frequencies as he now gets by using a heavy sound source in the room, which means vibrating the air past the orifice, (and in my opinion, but not in his, also means producing resonant effects in room and structure), he will have gone some way to prove his point. If, however, he does not, he will be confronted with another conclusion, likewise surprising and difficult to explain, namely, that the motion of the orifice relative to the air produces a totally different effect from a like motion of the air relative to the orifice.

I failed to get any selective response at all when vibrating the orifice, either with a liquid jet or with a flame, although the general response was the same as with the normal procedure, but it would, needless to say, be a great satisfaction to me to have the result confirmed by Dr. Sutherland.

The Sycamore Tree

IN Mr. Alexander Howard's interesting article in NATURE of March 18 on the sycamore tree, he did not mention the very remarkable aeronautical properties of its seed. It is the outstanding example of Nature making use of the autogyro in flight, and with a single-winged rotor.

Attempts have been made to copy this extremely efficient method of parachuting, so to speak, but so far nothing comparable with the efficiency of the sycamore seed has been evolved.

It is also interesting as a demonstration of animate Nature using revolving mechanism, of which she is usually shy, but in this autogyro single-winged sycamore seed we have an example of a rotary movement combined with advanced aeronautics.

BRABAZON OF TARA.

70 Pall Mall, S.W.1. March 20.

IMPROVEMENT OF ECONOMIC CROP PLANTS

In these days when our thoughts tend to be concentrated on battle areas and the production of munitions of war, it is refreshing to turn to the no less essential researches and activities which have as their aim the increased production and improvement of economic plants, an activity which will also be of benefit to the world when peace is restored. For his presidential address to the thirty-first Indian Science Congress held in January at Delhi, Dr. T. S. Sabnis chose as his topic the recent advances in botany in relation to improved crop production, and he is to be congratulated on the picture he has portrayed of the very varied avenues of botanical research which all converge and have their part in contributing to this ultimate aim.

Genetics is a relatively new science, and the astonishing advances since plant-breeding was placed upon a firm foundation by the re-discovery of Mendel's papers in 1900 justifies the placing of this subject in the forefront of such an address. In the period between the two Wars, a somewhat new impetus and outlook was introduced, particularly by the Russian plant-breeders under Dr. I. N. Vavilov, into the plant-breeding experiments, in that the latter were associated with widespread search and introduction of related cultivated and wild species from other parts of the world; this line met with considerable success, since new genes were introduced into the assemblage for assortment into combinations favourable for a wide variety of habitats; some of the wild species introduced genes of increased hardiness and disease resistance which would prove of very great value if combined with some of the properties of cultivated forms. The difficulties of inducing crosses between desired types were much reduced by the discovery that sterility of interspecific, or even intergeneric, hybrids might be overcome by artificial induction of polyploidy by the use of colchicine or X-ray treatments. Thus polyploid crosses between wheats and *Agropyrum elongatum* gave promise of perennial wheats with high yield and disease resistance combined with such hardiness that they would grow in regions previously considered impossible for cultivation of wheat. Polyploidy has also been shown to have its uses in contributing greater vigour to certain types and increasing the yields of certain plant constituents, such as the vitamin C content of tomatoes and the carotinoid content of maize.

Once the significance of introducing new types into the assemblage for interbreeding is realized, it is obvious that the plant geographer who studies the distribution of species, the pure systematist who names the plants, the ecologist who studies their relationships to the normal habitat, and the botanist who is interested in the subdivision of the species into varieties and microspecies, will all have their contribution to make to the successful cultivation of the plants concerned, and the possibilities of their hybridization and introduction as crop plants into new and previously uncultivated regions. The relation of the plant to its environment is in itself a large problem, and considerable light has been thrown on this type of study by the somewhat new aspects of the work elaborated by Clements. He has taken a more dynamic view of the vegetation, and his conception of climax, succession and conservation has stressed the importance of following the changes in a vegetation and has given results of importance particularly in relation to grassland and forest cultivation.

In the field of plant physiology, the work of Gardiner and Allard on photoperiodism has enabled a technique to be evolved for bringing plants collected from different climatic zones into the flowering condition at the same time and thus rendering their hybridization a possibility.

Another important aspect of plant cultivation in new regions was the discovery by Lysenko of 'vernalization'. Previously, many plants were confined within certain temperature zones, beyond which they could not be cultivated, but Lysenko showed that by careful regulation of temperature treatment of seed the climatic barrier could be broken down: for example, many varieties of winter wheats which would not ear when sown in spring could be made to do so by vernalization.

These are the main factors discussed by Dr. Sabnis in connexion with the production of new varieties of economic plants with improved qualities, or with wider ranges of cultivation in relation to climatic or soil conditions. He referred also to the significance of certain other aspects of botanical research, such as the utilization of certain chemicals to promote root-growth, which has played an important part in problems of vegetative propagation, and the recognition of the importance of secondary elements. It is not long since only those elements necessary to plants in relatively large amounts were recognized as essential, but it is now known that other elements such as boron, zinc, silicon, etc., may be responsible for deficiency diseases and failures of certain crops, though the quantities required are extremely small.

'CHROMOSOMIN' AND NUCLEIC ACIDS

In a recent article, Stedman and Stedman[1] have reported observations which they consider to indicate the existence of a special protein, termed 'chromosomin', in cell nuclei; and, on theoretical grounds, have endeavoured to ascribe to it several previously known phenomena considered to be due to other nuclear constituents, especially nucleic acids. As regards nucleic acids, Callan[2] has put forward the experimental data against their view; Stedman and Stedman[3] have based their reply to Callan largely on references to data from my laboratory. As no reference is given to the original papers, and I regard the comments as directly misleading, a brief correction appears to be called for; in particular, it seems desirable to indicate my view of the bearing of the ultra-violet absorption measurements on the 'chromosomin' question. This is all the more necessary as Stedman and Stedman, by the wording of their communication[3], convey the impression of a thorough study (p. 504, "if one examines Caspersson's work critically one will find, as he himself admits, that . . ."), whereas of some twenty-five publications bearing on this subject, issued from 1936 onwards, only the very first has been available in the original.

Stedman intimates (p. 504) that the absorption band in the nuclear material which I had attributed to nucleic acids may actually have been caused by tryptophane. In 1936 the first two absorption spectra obtained by a photographic process were recorded by me[4]. By evidence to which Stedman does not refer, it was shown that these spectra were due to a

nucleic acid band with an overlapping protein band. With the aid of photo-electric methods developed in and first described in the following year, 1937, absorption spectra of nuclear constituents could be taken with such exactitude that these spectra can be analysed into their components (for data regarding the requisite conditions for the measurements and the treatment of the preparations as well as technical data, see, for example, refs. 4, 5 and 6). The chief subject of all the subsequent investigations with this technique—in addition to the study of the nucleic acid distribution—has been precisely the distribution of the selectively ultra-violet-absorbing amino-acids, especially tyrosine and the tryptophane, about which Stedman inquires (see bibliography in, for example, ref. 7). These investigations have shown that nuclear structures in general are largely composed of proteins containing tyrosine and tryptophane, and moreover, especially in the metaphase chromosomes, nucleic acids. Whether any of these proteins may be of 'chromosomin' type it is, of course, impossible to judge from the absorption data. The localization of nucleotides in certain nuclear areas is in no way affected by a possible finding of acidic proteins in the cell nucleus. It should further be pointed out that there is no objection in principle to the supposition that proteins rich in glutamic acid may also be present in certain of those nuclear structures, which have been shown by staining experiments and absorption measurements to contain considerable amounts of hexone bases: the procedure used will not be affected by this component.

As it may be difficult at present to obtain access to Norberg's paper in England, it should be pointed out that here too the reference is misleading. Norberg[8] (p. 90) presents his results as preliminary, in so far as much wider fields of work than those which he has yet tackled have been opened up by his technique, for chemical study. The direct chemical determinations which he has already made on certain material are not, of course, 'preliminary'; they include his analysis of the Chironomus chromosomes.

The digestion methods have been discussed in detail by me in previous papers which Dr. Stedman has not apparently seen, to which the reader is referred[5] (p. 598). Their value must always be very limited. Stedman's observation, however, is valueless without experiments made in *exactly* similar conditions as those under which ours were conducted, as it is known that proteins with iso-electric point considerably below 5 are well digestible under those conditions.

Contrary to Stedman's statement, the ultra-violet absorption data to which he refers[1] show in the resting nucleus large amounts of proteins containing tyrosine and tryptophane.

The composition of the metaphase chromosome is very different from that of a resting nucleus, and it is to be regretted that it is still inaccessible to protein analysis by chemical methods. During the development of the metaphase chromosome in the resting nucleus a marked quantitative change occurs, in that the proteins containing tyrosine and tryptophane are largely broken down, while the ratio of the total tyrosine plus the total tryptophane to the total hexone bases is, in all probability, markedly shifted in favour of the latter. This last-mentioned development varies in degree in different kinds of animals: even closely related species may show considerable differences. The development of the sperm affords an interesting parallel. Analogous conditions in this field had already been shown by Miescher; he also stated that in some special cases the change proceeded so far that the major part, though never the total amount, of the sperm protein might consist of simple protamines. In a paper cited by Stedman, Miescher himself points out, in regard to sperm, that the main features of the development are similar in different cases, but that considerable differences occur in its terminating stages. Thus neither the results of the ultra-violet investigations nor those of Miescher's chemical researches are affected in the least degree by the 'chromosomin' question. It is conceivable that such a protein may exist; in that case, however, the content thereof, at any rate in the sperm of certain fishes, must be considered to be very low.

Summing up, it may be stated that the observations made with the aid of ultra-violet absorption measurements and associated methods, in conjunction with other microchemical experiments from recent years, are neither for nor against the occurrence of a protein of the chromosomin type in certain parts of the nucleus. Nor, on the other hand, does the assumption of 'chromosomin' as an integral constituent of the nucleus in any way affect the views which, chiefly with the aid of ultra-violet absorption measurements, have been advanced in regard to the protein and nucleic acid metabolism and the distribution of those substances in the nucleus. The views to which Callan has directed attention in regard to the distribution of the nucleic acid still hold good.

[8] Norberg, B., *Acta Physiologica*, Suppl. 14 (1943).

IN papers published mainly in Germany during the War, and possibly in later papers published in Sweden, none of which was or is accessible to us through our normal library facilities, Caspersson has put forward comprehensive theories concerning the chemical nature of the cell nucleus based upon ultra-violet spectrographic studies. While we have not seen these publications, they have been summarized by Darlington[1] in NATURE, and if this summary accurately represents Caspersson's views, as we have every right to think it does, we believe they cannot survive in the light of our work on chromosomin.

The dilemma in which our opponents find themselves will be seen from the following passage taken from Darlington's article: "The use of this technique has confirmed the picture so far outlined. But it has also gone much further. It has shown that heterochromatin and nucleolus agree in having a high histone content. On the other hand, in the euchromatin the regions between the chromomeres contain globulin-type proteins. These higher proteins are lost in metaphase chromosomes or ripe sperm." We wish to direct attention particularly to the last sentence, which makes it perfectly clear that, according to Darlington's summary of Caspersson's

work, the only proteins present either in metaphase chromosomes or in ripe sperm are histones or protamines. In his present letter, Caspersson virtually agrees to this view, although he does make certain hesitating reservations. Thus, he now states that in the metaphase chromosomes "the proteins containing tyrosine and tryptophane are *largely* broken down, while the ratio of the total tyrosine plus the total tryptophane to the total hexone bases is, *in all probability*, markedly shifted in favour of the latter" (our italics). Again, he states that "Miescher's chemical researches are [not] affected in the least degree by the 'chromosomin' question. It is conceivable that such a protein may exist; in that case, however, the content thereof, at any rate in the sperm of certain fishes, must be considered to be very low". If we recall that Miescher[2] calculated from his results that the dry, lipoid-free heads of salmon sperm contained 96 per cent of protamine (salmine) nucleate, it follows from Caspersson's statement that this material cannot contain more than 4 per cent of chromosomin, an amount which might easily escape detection by chemical methods. Caspersson's theories thus fall or stand according as chromosomin is or is not present in ripe sperm and metaphase chromosomes.

In the case of sperm, a decision presents no difficulty. The direct chemical examination of fish sperm which we have already made has shown that it contains considerably more than 4 per cent of chromosomin. The amount present cannot be determined with precision since, as we have already pointed out[3], only indirect methods are at present available for its estimation. These have, however, shown that approximately ten times as much chromosomin as the maximum which Caspersson's theories will admit is present in the dried sperm heads. This estimated figure, moreover, corresponds satisfactorily with the weight of crude chromosomin actually isolated from the sperm, and from this impure material chromosomin has been prepared completely free from any other known constituent of cell nuclei. Owing to difficulties in procuring material, we have not, it is true, yet had an opportunity of examining salmon sperm itself. Our results do, however, apply to herring sperm, which has also been stated[4] to consist entirely of protamine (clupeine) nucleate. That chromosomin is present in similar amount in salmon sperm is, however, evident to anyone experienced in the chemical examination of cell nuclei from a perusal of Miescher's papers. Had modern technical methods been available to him, we have no doubt that Miescher would have added to his discovery of nucleic acid and protamine that of chromosomin.

To demonstrate the presence of chromosomin in metaphase chromosomes is a more difficult problem. As Caspersson points out, they are "still inaccessible to protein analysis by chemical methods". Unfortunately for Caspersson's theories, however, there does exist a perfectly legitimate, although indirect, method of analysing metaphase nuclei (that is, chromosomes plus spindle) which we have actually employed[5]. When cells are undergoing constant proliferation without any accompanying differentiation, the proportion of cells in active mitosis at any instant is usually small. This is due to the fact that the actual division of the cell is a rapid process, whereas the interphase between successive mitoses is a much more prolonged one. Moreover, it is a cytological principle that the mitotic division of the nucleus is meristic, so that each daughter nucleus will have the same percentage composition as the mother nucleus but only half its mass. The protracted interphase which occurs between divisions is obviously necessary for the growth of the daughter nuclei, and, if no change occurs in the character of the cells, it is legitimate to draw the conclusion that this growth has no effect on the percentage composition of the nuclei. Analyses of nuclei from cells of the type described, of which tumour cells are a good example, have shown[5] not only that they contain chromosomin but also that this protein constitutes a greater proportion of the dry nuclei than is the case with permanently resting nuclei such as those from thymocytes and avian erythrocytes. This result is again in direct conflict with Caspersson's conclusions.

But we do not depend solely on the above arguments to prove that chromosomin is the principal constituent of chromosomes. The properties which the purified material possesses indubitably point to the same conclusion. Not only does it, as we have previously mentioned[1], behave towards basic dyes in the same way as do the chromosomes, but also the remarkable avidity with which it takes up developed nucleal stain both in the purified state[6] and as a component of the chromosomes[7] leaves no doubt whatsoever as to its position in the metaphase nucleus. Moreover, its physical properties point in the same direction. Nobody familiar with the properties of histone could possibly imagine that this base could, even in combination with nucleic acid, form structures like the chromosomes which resist the action of the drastic fixatives sometimes employed in staining processes. Chromosomin, on the other hand, possesses chemical and physical properties which are eminently suited to withstand this treatment. Further, histones and protamines are too simple in structure, as Mathews[8] has pointed out, to account for the hereditary functions of the chromosomes. Chromosomin, however, is a much more complex protein which could, and no doubt does, subserve this function.

Caspersson's own spectrographic measurements are not in contradiction with our conclusions, although he seems reluctant to admit the fact. Caspersson states that his absorption spectra published in 1936[9] were shown to be due to a nucleic acid band with an overlapping protein band. His proof has eluded us, but he does say (p. 95): "Mit grosser Wahrscheinlichkeit ist die Verschiebung auf eine im Chromosom enthaltene Eiweisskomponente züruckzuführen, welche eine Absorptionskurve gleich in Fig. 12 mit einem schwachen Absorptionsmaximum 2800AE hat. Diese könnte bei einer Konzentration, welche in keiner Weise mit der der Nukleinsäure vergleichbar ist, vollkommen die Verschiebung erklären". We must point out, however, with regard to this explanation, that Caspersson estimates that the absorption produced by the chromosomes is equivalent to that of a 10 per cent solution of nucleic acid. Elsewhere (p. 33) he shows that a solution of this concentration absorbs 90 per cent of the incident light, whereas a protein layer (serum albumin) in the same concentration and under the same conditions absorbs only 2 per cent. It is clear from this that a concentration of protein equal to that of the supposed nucleic acid in the chromosome would have a negligible effect on the final curve. Yet in Caspersson's chromosome curve the protein so dominates the absorption that the maximum appears at a wave-length of

2750 A., which is characteristic of tryptophane, rather than at 2600 A., which is characteristic of nucleic acid.

It is evident that the application of ultra-violet spectrophotometry to structures such as nuclei in which the components are of unknown composition and are present in unknown concentration can give no certain information regarding the chemical nature of those structures. It follows, further, that the view that chromosomes consist mainly of nucleic acid and contain protein in a concentration "welche in keiner Weise mit der der Nukleinsäure vergleichbar ist" cannot be sustained. No doubt as knowledge of the chemistry of the nuclear constituents increases it will be possible to interpret some, if not all, of Caspersson's measurements. Until then, it would be rash to accept the many speculations which have been based upon his work, particularly those involving the postulated presence of ribose nucleic acid in the nucleoli.

Caspersson asserts that Norberg's analyses of Chironomus chromosomes are not to be regarded as preliminary ones. If we mistook the meaning of Norberg's apparently ambiguous statement on this subject, we can only plead that we were unconsciously influenced by the nature of the results themselves. Most of the analyses were carried out on chromosome balls, which obviously consisted of the chromosomes plus the bulk, if not all, of the nuclear sap. The main series of experiments gave values varying from 0·11 to $0{\cdot}48 \times 10^{-3}$ γ P. Thus, the maximum value obtained was more than four times the minimum one. We quite appreciate the difficulties of carrying out such experiments, but surely results of this nature should not be offered as confirmation of other work.

We do not propose to discuss further the question of the distribution of nucleic acid in the nucleus. Our position has been adequately stated in our previous communication[6] and we see no reason to change the views there expressed.

SCIENCE AND TECHNOLOGY IN THE POST-WAR WORLD

THE address entitled "The Promise of Technology" which Dr. F. B. Jewett delivered in the second series of conferences on "Post-war Goals and Economic Reconstruction", held under the auspices of the Institute on Post-war Reconstruction of New York University (*Science*, 99, 1–6 ; 1944), covers a number of points of high significance in the discussions at present proceeding in Great Britain with regard to the encouragement and endowment of fundamental research and the supply of research workers. Dr. Jewett, who is a vice-president of the American Telephone and Telegraph Co., points out that the technologist in the biological sciences during war-time is generally continuing in a different sector, on an enlarged scale and with clinical facilities not available in peace-time, the normal course of everyday life, and that most of what he has learned will be immediately applicable to peace-time. On the other hand, much of the technological applications of the physical sciences in war has no prospective application in peace-time. Dr. Jewett states that technology is the application of fundamental scientific discoveries and the employment of scientific methods for useful or desirable purposes ; except incidentally, technology as such is not concerned in the production of new implements of knowledge.

Normally, the scientific and technical world is divided roughly into two main groups : those concerned primarily with extending the boundaries of knowledge, developing new facts and learning more accurately the characteristics of old ones, without regard to their possible ultimate utility ; and those concerned in finding ways and means for the more effective application of fundamental science to the uses of mankind. As an integral part of its work, the first group has also the continuous production of new investigators for fundamental science and the training of men and women for industrial research.

Fundamental research, Dr. Jewett points out, flourishes best when there is complete freedom of intercourse and discussion and publication of results among the scientific men of the world, not merely within a given nation. Under normal conditions, the *modus operandi* in the second group is similarly that of free intercourse and interchange of ideas. The interruption of intercourse in war, with the consequent tendency for men, whether in fundamental or applied science, to work in water-tight compartments, leads to unnecessary duplication of work and general handicaps. Taken with the interruption and discontinuance of much fundamental research during war-time because it has not apparent immediate bearing on the war effort, and the deflexion of prospective recruits for such research to war activities, we are likely in consequence to find ourselves at the end of the War with a frontier of fundamental knowledge little beyond that which existed at the outbreak of war, although somewhat different in aspect. Advances in war-time have represented essentially a more intense utilization of existing knowledge and application of established techniques, and not new knowledge or technique itself. By and large, Dr. Jewett considers that during the period of active warfare there is an almost complete stagnation in the fundamental sciences. In addition, he considers that we shall have a paucity of young men and women broadly acquainted with established knowledge and rigorously trained in scientific method, in spite of the immense number who have become skilled technicians in limited fields, and a population with some real understanding of science and technology.

The cessation of hostilities, Dr. Jewett considers, will see an immediate disintegration of the present machinery of science and technology. Scientific men will wish to resume the pursuit of new knowledge in a free intellectual world, while industrial research workers and technologists will seek to take up again their former investigations and to fill in the gaps made by the inroads of war and the forced laying aside of promising new applications. There will be a dearth of highly trained men for fundamental research for

general application, and a large number of men trained in specific applications.

Pointing out that the new and wider understanding of science and technology on the part of the population in general is likely to lead to government playing a bigger part in the development of science and technology than in the past, Dr. Jewett insists that the functions of a director of research are essentially to provide a proper atmosphere in which men with creative ideas can work freely; to map out the general fields in which progress appears to lie; and finally to weigh the results of research work with many other factors in deciding how to proceed.

A number of Dr. Jewett's points have already been made in the report of the Parliamentary and Scientific Committee on "Scientific Research and the Universities"; the picture in Britain is not likely to be very dissimilar from that in the United States. In spite of reference to the question of freedom of intercourse and discussion and publication of results in the House of Lords debate on scientific research and elsewhere, this aspect has as yet attracted little attention, although there are signs of a more generous attitude towards publication on the part of industrialists. In that respect, however, apart altogether from the inevitable restrictions imposed by the War, British industry has lagged far behind industry in the United States. Dr. Jewett's address is to be welcomed on that ground alone—that it emphasizes once more the vital importance of freedom of communication to all creative and fundamental scientific investigation. No post-war plans for stimulating research in industry or elsewhere will have their full effect unless they establish the conditions in which such intercourse has the maximum encouragement.

GEOPHYSICAL EXPLORATION IN CANADA AND THE UNITED STATES

Evidence concerning geological formations near the surface of the earth, and down to depths of, say, less than one mile, can be obtained by geologists by examining the strata immediately accessible at the surface, and by inference from known similar formations, by skilfully extrapolating down to the required depth. When this process becomes somewhat risky and the formations are economically important, the sinking of boreholes at carefully selected critical places is then undertaken. These, however, are normally costly, and in their place, many companies have undertaken in recent years the geophysical surveys which, though less costly than the sinking of boreholes, have provided just that extra information which the geologist required, and that in reasonable time.

The geophysical methods of surveying may roughly be divided into four types, namely, the electrical, gravitational, magnetic and seismic, and in each of these, due to the large amount of experimental work done, great improvement in technique and in the consequent accuracy of the results has been achieved. The Rev. James B. Macelwane, *S.J.*, of St. Louis, has recently reviewed the work done in the United States and Canada during the years 1924–39 ("Fifteen Years of Geophysics: a Chapter in the Exploration of the United States and Canada, 1924–1939." By James B. Macelwane. *Geophysics*, 5, No. 3; July 1940).

Before 1924, according to the author, knowledge of geophysical methods of prospecting was not widely spread in America. In March of that year the Nash salt-dome was discovered by the torsion-balance method; in October the Orchard dome was discovered by the seismic method, and the Long Point dome by the torsion-balance and seismic methods. The current value of a new dome was between 500,000 and 1,000,000 dollars; so with the beginning of 1925, the use of the torsion-balance and seismic methods began to expand rapidly in America.

Seismic Methods. The years 1925–29 constitute the era of whirlwind seismic refraction reconnaissance. The mechanical seismographs gave place to electromagnetic seismographs, and the sound wave to precise surveying and radio signals. Up to 1929, according to Heiland, considerable areas had been explored in Alabama, California, Kansas, Louisiana, Mississippi, New Mexico, Oklahoma and Texas. Karcher, Eckhardt and McCollom had been experimenting with a reflexion seismograph, and it was at this stage that the Geophysical Research Corporation took the matter up and developed the modern multi-trace reflexion seismograph which has played so large a part in subsequent work. The seismic reflexion method has played an important part in this work of determining underground structure by means of artificial earthquakes since the year 1929.

In the United States of America the mid-continental area was the first to be surveyed in this way, and it was not until 1932 that this method was extensively used in the Texas-Louisiana Gulf Coast area. Now the seismic reflexion method is second only to the drill in the precision with which it is able to determine depths and outline structures. Secrecy is still maintained by some companies concerning the extent of this type of work undertaken by them.

Magnetic Methods. The magnetic method was in extensive use in North America from 1927 onwards. It is relatively inexpensive and the use of magnetometers simple, but so far as petroleum is concerned the magnetometer results are difficult to interpret with precision. Consequently, for petroleum surveys, the use of the magnetic method had largely ceased by 1931 for anything except preliminary surveys. In the mining field, however, its use has been practically continuous. Most of the central plains and coastal areas of the United States had been surveyed by this method up to 1939, and in Canada it had been used in the Provinces of Quebec, Ontario, New Brunswick, Nova Scotia and British Columbia.

Gravitational Methods. The two types of instruments used for these surveys are the torsion balance and the gravity meter. The torsion balance had excellent success in the Gulf Coast from the start in 1924; but it had reached its peak in 1931 and by 1937 was very little used in North America. Fieldworthy and sufficiently sensitive gravimeters were developed during 1937–38, and in the period immediately prior to the present War, field work with these was being conducted over extensive areas in the United States of America. According to Macelwane, so rapidly may these surveys be conducted, and so difficult and slow is the process of adequate interpretation of the data thus obtained, that there has accumulated in the files of most companies an undigested mass of differential or relative gravity values the meaning of which is not altogether clear.

Electrical Methods. These have proved most useful in the mining field. They were found to be inferior to the seismic and gravity methods in prospecting

for petroleum. Some of the electrical methods are used with geochemical prospecting because there would seem to be a connexion between certain electrical anomalies and geochemical prospects. By 1929, electrical surveys had been conducted in Alaska and sixteen States in America besides the Canadian Provinces of British Columbia, Manitoba, Nova Scotia, Ontario and Quebec, and in Newfoundland.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Saturday, April 22

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 2.30 p.m.—Dr. J. Blair Hartley: "The Future of Radiology in Obstetrics".

INSTITUTE OF PHYSICS (INDUSTRIAL RADIOLOGY GROUP) (at the Royal Institution, 21 Albemarle Street, Piccadilly, London, W.1), at 2.30 p.m.—Mr. W. H. Glaisher, Dr. W. Betteridge and Mr R. Eborall: "The Mottling of Aluminium Alloy Radiographs".

INSTITUTE OF PHYSICS (SCOTTISH BRANCH) (in the Chemistry Buildings, The University, Glasgow), at 2.30 p.m.—Inaugural Meeting. Mr. E. R. Davies: "High-Speed Photography, and its Applications in Science and Industry".*

Monday, April 24

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir A. H. Roy Fedden: "The Future of Commercial Aviation" (Cantor Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Fuel and Mechanical Power" (to be opened by Mr. J. F. Field).

Tuesday, April 25

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. A. P. van der Post. "Secondary Industries in South Africa".

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Mr. David M. Fulcomer: "Bereavement as a Field for Research; an Introduction with Special Reference to Recent Research on Bereaved Spouses".

Wednesday, April 26

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. G. Samuel. "Some General Aspects of Potato Production in Great Britain"

PHYSICAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. Joel H. Hildebrand: "The Liquid State" (Twenty-eighth Guthrie Lecture).

Thursday, April 27

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Prof. E. C. Stoner, F.R.S.: "Magnetism in Theory and Practice" (Thirty-fifth Kelvin Lecture).

BRITISH INSTITUTION OF RADIO ENGINEERS (LONDON SECTION) (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 6.30 p.m.—Mr. P. Adorjan: "Development of Wired Broadcasting"

Saturday, April 29

BRITISH RHEOLOGISTS' CLUB (at the Shirley Institute, Didsbury, Manchester), at 10 a.m.—Discussion on "Elastic Behaviour of Textile Materials".

ASSOCIATION FOR SCIENTIFIC PHOTOGRAPHY (at the Caxton Hall, Westminster, London, S.W.1), at 2.30 p.m.—"Photography as a Tool in Agriculture" (Papers will be read by Dr. E. N. Crook and Mr. V. Stansfield, and by a Representative of the National Institute of Agricultural Engineering).

PHYSICAL SOCIETY (at the new Clarendon Laboratory, Oxford), at 2.30 p.m.—Prof. Joel H. Hildebrand: "The Liquid State" (Twenty-eighth Guthrie Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT MASTER to teach ELECTRICAL ENGINEERING to Ordinary National Certificate standard in the Openshaw Technical School—The Director of Education, Education Office, Deansgate, Manchester (April 28).

LECTURER (temporary) in the PHYSICS DEPARTMENT—The Principal, Heriot-Watt College, Edinburgh (April 28).

LECTURER (full-time) IN CHEMISTRY—The Principal, Acton Technical College, High Street, London, W.3 (April 29).

PSYCHIATRIC SOCIAL WORKER to work with the Psychiatrist and Educational Psychologist in the Child Guidance Clinic—The Director of Education, Education Office, Town Hall, Barnsley (April 29).

RESEARCH METALLURGIST, preferably with knowledge of ENGINEERING, by well-known North Country firm specializing in the Use and Heat Treatment of High-Carbon and Alloy Steels—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.2019XA) (April 29).

PROFESSORSHIP OF ENGINEERING SCIENCE—The Registrar, University Registry, Oxford (April 30).

EDUCATIONAL PSYCHOLOGIST, and a PSYCHIATRIST SOCIAL WORKER—The Secretary for Education, County Education Offices, Northampton (May 1)

LECTURER (full-time) IN CHEMISTRY at the Cardiff Technical College—The Director of Education, Education Offices, Cardiff (May 1).

CHAIR OF PHILOSOPHY at the University of the Witwatersrand, Johannesburg—Dr. William Cullen, 4 Broad Street Place, London, E.C.2 (May 1).

ENGINEERING WORKSHOP INSTRUCTOR in the Mechanical Engineering Department, a TEACHER OF SCIENCE AND MATHEMATICS, and a TEACHER OF WOODWORK, BUILDING CONSTRUCTION AND GEOMETRY, in the Junior Technical School of the Barnsley Mining and Technical College—The Principal, Technical College, Church Street, Barnsley (May 1).

LECTURER IN ORGANIC CHEMISTRY in the Brighton Technical College—The Education Officer, 54 Old Steine, Brighton (May 4)

VICE-PRINCIPAL of the Brighton Technical College (the post will be embodied with that of Head of the Civil Engineering and Building Department)—The Education Officer, 54 Old Steine, Brighton (May 4)

DISTRICT ENGINEER by the Ceylon Government Railway—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.926A) (May 10)

SENIOR POST under the AERONAUTICAL INSPECTION DIRECTORATE (applicants should possess a first-class Honours Degree in Physics or a recognized equivalent, have had industrial radiological experience, be conversant with the various modifications of the technique of X-ray crystal analysis, and be capable of carrying out independent *ad hoc* scientific investigations in electro-physics)—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. A.499A) (May 10)

DIRECTOR OF THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

CHAIR OF NATURAL PHILOSOPHY, United College, St. Andrews—The Secretary, The University, St. Andrews (June 15).

TEACHER (full-time) in the MATHEMATICS AND PHYSICS DEPARTMENT—The Principal, Municipal Technical College, Hopwood Lane, Halifax

MEN qualified to teach MATHEMATICS, SCIENCE and MACHINE DRAWING, at the Wakefield Technical College—The Director of Education, 27 King Street, Wakefield.

GRADUATE ASSISTANT (temporary) with special qualifications in MECHANICAL ENGINEERING, a GRADUATE ASSISTANT (temporary) with First- or Second-Class Honours or Higher Degree in either MATHEMATICS or PHYSICS, and a well-qualified ASSISTANT (temporary) with trade experience for ENGINEERING WORKSHOP PRACTICE—The Principal, Mining and Technical Institute, Neath, Glam.

PRINCIPAL OF THE ROYAL HOLLOWAY COLLEGE—The Secretary to the Governors, Royal Holloway College, Englefield Green, Surrey

LOCATION OF INDUSTRY AND PROVISION OF MAN-POWER

THE memorandum, "Considerations Affecting Post-War Employment in the North-East", which has been issued by the Northern Industrial Group, consisting of employers and trade-union leaders in northern England, and which has been sent to the Minister of Reconstruction, is not only of interest in relation to post-war reconstruction and employment policy and the change from a war to a peace economy. It may well be compared with the report submitted in May 1935 to the District Commissioner for Depressed Areas by a joint committee of the local sections of the Society of Chemical Industry, the Royal Institute of Chemistry and the Chemical Society, and with a subsequent report, "The Industrial Position of the North-East Coast of England", issued later in the same year by the staff of the Economics Department of Armstrong College, Newcastle on Tyne. The conclusions reached in the latter report appear to be fully confirmed and to be as valid to-day as eight years ago, and substantially the same is true of the other report and especially of the section contributed by the sub-committee on science and industry.

The Northern Industrial Group in its memorandum points out that the War has brought no real change to the industrial structure in the area. That structure remains much as it was in the days of the depression ; and unless adequate preventive measures are taken there is real danger that the employment and standard of living of people in the area will again be seriously threatened after the present War. Still more disturbing, not to say disappointing, is the absence in this memorandum of any real evidence that the lessons set forth so clearly in the reports from Armstrong College and the joint committee of the chemical societies have been learnt, or of the extensive application of scientific methods to those industries which situation and local raw materials make possible. Something more than vigorous action on the part of the central Government still appears to be required to eliminate the threat of large-scale unemployment in the area ; and while responsibility for the position cannot fairly be laid entirely on the industrial leaders of the area, they have yet to clear themselves of the charge of absence of foresight and neglect of science brought against them eight years ago.

There are other respects in which the general situation has changed ; but the indictment in the earlier reports needs to be kept in mind the more because of the shift in emphasis from local to national responsibility, which has been accentuated in the interval. It is now widely recognized, and rightly, that certain basic decisions as to policy must be made by the central Government before local authorities or even regional authorities can act wisely or effectively. The memorandum of the Northern Industrial Group assumes first, for example, that a national economic policy will be adopted, and that to secure ample employment in reparation and reconstruction work at home and abroad the Government

will continue to control production in some way for an interim period of unknown length after the War, with a gradual change to a peace-time economy. In this interim period, any deficiencies in employment in Great Britain should be met by work on the many necessary schemes for public works. National policy should also assure a stable level of employment in the heavy industries and in agriculture.

Even with such measures, on the basis of the immediate pre-war industrial structure of the region, there will be a surplus of some 130,000 persons for whom employment will have to be found, and such estimates of the post-war capacity of the heavy industries in the area as the Group is able to make suggest that new forms of occupation will be required for more than 100,000 people, even without allowing for women seeking employment. The Group, however, firmly rejects the large-scale transfer of population from the north-east of England to other areas as socially and economically undesirable; although there is nothing in the memorandum to indicate dissent from the view implicit in the Beveridge Report that greater mobility of labour generally is desirable, if not essential. The memorandum holds that the future policy should be to employ people in their own surroundings. The Group believes that the north-east of England has its own background and a tradition of virility and of independence which is an asset to the nation and should be preserved. Social security may, in fact, increasingly necessitate the adjustment of employment to the distribution of population.

Such considerations lead to the conclusion that the solution of the industrial problem of the north-east of England lies in the development in the area of a much greater variety of industries making highly developed products suitable for export as well as for the home market. Such a development would mitigate a permanent change in employment by heavy industry and provide a reserve of employment to meet fluctuations. In particular, further developments in the area of the processing of coal to oil, plastics, etc., are recommended, and the memorandum urges that whatever emerges as part of Great Britain's fuel policy from experimental work now in progress should be concentrated in this and other coal-producing regions. Again, certain parts of the area should be cleared of derelict buildings to encourage development, and any further capacity required for war production should be located in the area. After the War, an active policy of building factories in the area to make up for the effects of war development should be prosecuted, with the transfer of factories rather than labour.

All this, and the continuance of the measures adopted before the War to bring light industries to the north-east of England, involves a national policy for the location of industry, and the memorandum once more directs attention to the necessity for implementing the recommendations of the Barlow Commission. The reference to this question which Lord Woolton made in his recent statement shows that the Government is already giving some attention to the problem of structural unemployment, and Lord Woolton suggested that the Government might use the disposition of State factories to assist the creation of a diversity of industries in areas such as the north-east coast. Mr. Dalton had already broached the idea that such factories might become the nucleus of new trading estates, and it may be that the Government is giving more attention to the location of industry than has appeared in its pronouncements.

Other recommendations in this memorandum touching on the same question are the consideration of freight rates and their effect on the location of new industries, the provision of national finance for the local reorganization of housing and industry in certain areas such as part of south-west Durham, amendment of housing legislation to allow of more flexibility and a closer co-ordination with industrial policy and the provision of additional trading estate facilities in the area. Once again the multiplicity of local authorities, particularly on Tyneside, and the limitations of the rating system, with the consequent encouragement of sectional and parochial views, receive strong comment, and here again it is urged that the areas of local authorities should be re-drawn to give larger and more effective units. In this the memorandum is clearly alive to the importance of maintaining local interest, attracting industry to take a larger share of this form of public service, and giving the local authorities wider and more effective scope for co-operation with the industrial community as a whole; its final recommendation is the formation of a local development organization to continue the study of these problems, to co-ordinate them and keep them before the attention of the Government, utilizing the experience of the pre-war North-East Development Board and subsequent experience.

The memorandum clearly fits into the pattern of post-war employment policies which was covered broadly by Lord Woolton's statement in the House of Lords on February 15. Like that statement, it visualizes the need for some measure of Government control at least during the first two of the three economic phases through which we must pass during the immediate post-war years, and of definite guidance if not control during the third phase. Once again it emphasizes the necessity for Government decision and the elaboration of a policy in regard to such matters as the location of industry, before either particular industries or regions can proceed to elaborate their own plans. Furthermore, any such plans must be related to a national policy and plan, and clear guidance must be given as to the principles on which national and regional plans are to be based. Only then, and when some real attention has been given to the way in which such developments will react on the position and resources of local authorities and their relation to the central Government, can a practical scheme and time-table of demobilization be worked out and explained to those concerned.

Lord Woolton's own statement was admittedly incomplete, for it disregarded the international aspects of employment policy, control of raw materials, trade and currency policy. None the less, the ground he covered, leaving out of account the Service ministries that will be concerned with demobilization, relates to policy which must come under at least six depart-

ments—the Treasury, the Board of Trade, and the Ministries of Production, Supply, Aircraft Production and Labour, apart altogether from the authorities concerned with building and physical reconstruction. The impossibility of fitting departmental policy and measures together, without the prior and clear enunciation of the main lines and principles of policy at the centre, in a way that will solve the long-term employment problem, and permit a smooth transition from a war to a peace economy could scarcely be demonstrated better. Nor can even the essential task of educating public opinion as to what is involved proceed until policy has thus been enunciated.

The necessity for such publicity is well brought out in an able analysis of the whole question of demobilization and employment, which frankly faces the general question of the depressed areas, contained in a broadsheet (No. 217) recently issued by Political and Economic Planning. The problems which will confront us in remobilizing for peace are examined in the light of the experience of the War of 1914–18, and while the necessity of striking a balance between economic needs and the desires of service men is recognized, the imperative necessity of a publicity campaign, planned with all the vision and skill at the Government's command, to explain the why and how of policy, is equally stressed. No scheme will avoid all difficulties, but if the situation is fairly and simply explained to the millions of service men and war workers, it would do much to temper impatience and to curb over-sanguine expectations.

The preliminary analysis in the broadsheet follows the lines of Lord Woolton's statement. For several years the demand for man-power will far exceed the supply; quite apart from war requirements in the Far East, massive dammed-up demands for peace-time goods will place a heavy load on industry for some time to come. Inflation rather than general unemployment will be the danger. Social equity and economic order alike will require a system of priorities, and these must be carefully balanced to ensure that demands are in harmony with industrial capacity.

Dealing first with military demobilization and viewing it as a part of the vast business of re-orientating the war economy, the broadsheet points out that military factors will determine the rate of discharge. With regard to the question whether the rate of discharge should be left simply to military considerations or further controlled by the availability of jobs, the broadsheet quotes with approval the official view that the rate should be governed solely by operational requirements. The principles governing the order of release are likely to give far more difficulty, and here the wisdom of public announcement by the military authorities at an early date of the general principles they propose to adopt, and the strict observance of the principles formulated, are of paramount importance. The first rational principle is that industry's needs should be paramount: the speed with which the wheels of peace-time industry can be restarted will depend in part on the availability of certain key men. Some enterprises will be unable to revive quickly unless they are able to obtain the services of skilled men now in the Armed Forces. To make personal and family status the only test might quickly lead to chaos. Some account must be taken of the industrial background at home, though none the less policy must be affected by what service men will regard as fair.

The essential proposals of the report on demobilization issued by the Liberal Party Committee are in striking harmony with many of the views of P E P. The features of the Liberal Party's report are the emphasis placed on the need for speed in carrying out demobilization, and the insistence on the improvement of conditions of pay and service in the Armed Forces so that it may be possible to recruit without delay a professional army for the maintenance of order abroad. The report urges that it is the negation of both democracy and justice to retain the principle of compulsion in relation to military service merely to avoid the introduction of adequate scales of pay.

Plans for re-settlement in civil life are of capital importance in any demobilization scheme, and this report and the broadsheet both stress the necessity for opportunities for re-training and education. The report would make the continued receipt of pay and allowances, and certainly of unemployment benefit, after the first three months, conditional on attendance at training centres by those who had been unable to obtain civilian employment, while the broadsheet urges a serious effort to mobilize as many teachers as possible for this purpose. The Government plans are welcomed, especially the appointment of the strong committee under Lord Hankey to advise the Appointments Department of the Ministry of Labour. The debates on the Reinstatement in Employment Bill have made it plain that reinstatement is only part of a bigger problem. The crux of the matter is to ensure employment, and the broadsheet, in discussing what may be termed the reception end, suggests that the employment exchanges must be made both more efficient and more acceptable to employers and employees alike than they were before the War. It is also suggested that the exchanges might draw on Army experience with intelligence and aptitude tests for fitting the right man to the right job, and take over some of the trained Army personnel. Records which have been accumulated by the Services should be made available to the exchanges, so that they have information not only about a man's technical training and service experience but also about his general aptitudes.

Turning then to the question of industrial employment, the P E P broadsheet has no hesitation in assuming that a high demand for labour will continue. Apart from the military demands for the War in the Far East, production in general may not slacken nearly so much as many people think; there will be a vast demand waiting to be satisfied in the civilian field, and there will be keen competition to utilize any resources which may be released from the war effort. Export, for example, must rank as a high priority. It is of the first importance that Britain should not let domestic demands so swamp productive capacity that export markets are lost by default. Consumers will also wish to make good the accumulated deficiencies of war-time, and there will be the more

serious deficiencies in the nation's capital equipment to make good, notably in building; finally, Britain will have to bear her share of the cost of relief for the great areas of the world which have been devastated or impoverished by the Nazis or the Japanese.

The great problem in the view of P E P will be how to secure enough labour for the jobs that will need doing—for continued military production, for exports, for housing, for the manufacture of consumers' goods for relief. Accordingly, it will be essential for the Ministry of Labour to retain its powers under the Essential Work Orders. As a consequence of the prevailing shortage, the labour factor will continue to be of high importance in the general economic strategy, and the position of the Ministry of Labour as pivotal as it has become in the later stages of the War.

Two provisos are made to the general proposition that there will be a shortage of labour for some years after the end of hostilities in Europe. First, as already indicated, some temporary unemployment due to the transition from one type of production to another, and from war to peace production, is inevitable. Secondly, employment opportunities will not necessarily be distributed in accordance with the supply of labour. There may be pockets of unemployment, and the Northern Industrial Group in its memorandum directs attention to this outstanding danger which may threaten other areas besides the north-east coast of England.

P E P urges that it should be one of the great aims of Government policy to encourage industrial development in these areas. The end of the War should provide a great opportunity to establish in the former Depressed Areas new enterprises giving a better balance between foreign and home markets, and between light and heavy industries. The Government's many powerful instruments of control place it in a strong position to prevent local unemployment either in the short or in the long run. As the chief customer for most of the country's industry, the Government will possess in the process of terminating its contracts a strong lever which could be used to minimize or prevent local unemployment. The disposition of plant and equipment owned by the State and the power to license materials could all be used to prevent local unemployment, for example, by implementing trading estates, new centres of light industry and developing new processes and raw materials, as the president of the Board of Trade has already indicated.

Despite the complexity of the problems involved in military demobilization and industrial re-adjustment, there is therefore no reason for pessimism as to the employment situation in Great Britain; there should be little danger of general, though there will be some danger of local, unemployment. The process of adjustment can, however, only be made tolerable by planning, and by the retention of some at least of the measures of war-time control. If that is to succeed, the reasons for planning and control must be made plain to all, and their purpose clearly and honestly explained. That is as essential as it is that the Government should make its decisions and announce its central policy as early as possible, so that regional and local action is possible in harmony with the national plan, and as large a measure of initiative and freedom afforded to local enterprise as is consistent with orderly transition from war to peace.

JUDGMENT ON PLANNING

T V A

Adventure in Planning. By Prof. Julian Huxley. Pp. 142. (Cheam: Architectural Press, Ltd., 1943.) 8*s*. 6*d*.

THE Tennessee Valley Authority has now been established for ten years, and the experience of a full decade renders possible an attempt to assess its achievements and their significance, both in relation to the problems of regional planning in Great Britain and to the no less difficult range of administrative problems involved in public control and the relations between local and central government. In giving us the first detailed account published in Great Britain of this achievement, Dr. Huxley provides an admirable complement to Prof. C. Herman Pritchett's "The Tennessee Valley Authority: a Study in Public Administration", copies of which only now appear to have reached this country, although it was published in the United States in 1942.

Prof. Pritchett's book, as its sub-title indicates, is in the sequence of Prof. R. E. Cushman's study "The Independent Regulatory Commissions", from which consideration of the Tennessee Valley Authority was expressly excluded. It is concerned essentially with the political and administrative problems of the venture and makes a striking appendix to the report of the President's Committee on Administrative Management. Dr. Huxley, on the other hand, while not ignoring those aspects, places his main stress on the social and broader technical aspects of what he rightly terms an experiment or adventure in planning. His able presentation of the whole range of problems, and his skilful and lucid delineation of the fundamental questions or principles involved, coupled with the admirable photographs with which the book is illustrated and a good bibliography, should make his book as welcome to the serious student as to the general reader.

For the scientific worker, this account of the use of the scientific method of research, survey and experiment in dealing with great and complex social and economic problems is of special interest. Even those who have some knowledge of the achievements of the Tennessee Valley Authority in regard to power supply and to soil conservation may well be surprised at the picture Dr. Huxley gives of the effects of this great experiment on agriculture, health, labour, education, architecture and design. From the outset, the Authority has realized the enormous potential value of its reservoirs for recreation, and from this has proceeded to plan for the same development of all aspects of recreation in the Valley. No section of Dr. Huxley's book is more suggestive at the present time than that in which he describes the work of the Authority in regard to parks and wild life, and it deserves the close attention of all those concerned with present proposals for nature reserves or national parks in Britain.

Continuous research and survey are the essence of any large-scale planning, but many scientific workers will learn for the first time in these pages of

the wide range of research for which the Tennessee Valley Authority has been responsible in the ten years of its existence, apart altogether from its basic surveys of the mineral and agricultural resources of the Tennessee valley. Particularly is this true of its research at the consumer end, for example, on the design of agricultural machinery suited to the physical and economic peculiarities of the region; while Dr. Huxley's reference to the archæological investigation of the area to be flooded at the Pickwick Dam site, directed by the Authority in co-operation with the University of Alabama, makes a startling contrast with the way in which we have permitted quarrying to endanger the Roman Wall, to name only one recent example.

Dr. Huxley's account of the achievements of the Tennessee Valley Authority is the more impressive because he brings out the dangers or weaknesses as well as the advantages of regional planning on this scale. Compulsory powers, he points out, should never constitute more than the skeleton of planning. The living plan itself must evolve and grow, and can only do so on the basis of co-operative participation—both co-operation with other Government bodies and official and unofficial agencies, and co-operation with the people of the region, through arousing their sense of participation and making them feel that it is their plan and that they have a real share in bringing it to fruition.

It is for the way in which it has endeavoured, largely with success, to secure such co-operation that the Tennessee Valley Authority is of such prime importance in relation to post-war reconstruction. Its decentralized administration, as Dr. Huxley emphasizes, gives it a further claim to close study in this connexion and has contributed largely to its success. The way in which this has been achieved—by making the greatest number of decisions on the spot, by developing so far as possible the active participation of the people themselves, by co-ordinating in the field the work of all other agencies concerned, and by decentralizing the idea behind an administration so that its planning becomes a part of public opinion—has a vital bearing on those problems of centralization, regionalism and local control with which we are already being confronted in almost every one of the fields in which we are tentatively approaching the problems of the post-war world.

Dr. Huxley himself indicates the significance that this great experiment has for such war-time developments as the Middle East Supply Council or the Caribbean Commission, or for such suggestions as that for a post-war Danube Valley Authority. Readers of Dr. Huxley's book should be able to form some independent opinion as to how far Mr. Hugh Quigley is right in his contention in a recent article in *Agenda*, on "The Highlands of Scotland: Proposals for Development", that the riches of the Highland landscape, life and enterprise should be enjoyed as a national possession or in his suggestions for their preservation.

Dr. Huxley's book should stimulate much fresh thought about this and other problems of depressed areas and regionalism in Great Britain. Its topical bearing, no less than its admirable presentation, should ensure it a place on the shelves of all concerned with problems of reconstruction and regional planning, and the application of scientific method in the solution of social and economic problems.

R. Brightman.

THE SOCIOLOGY OF CRIME

Race and Crime

By Willem Adriaan Bonger. Translated from the Dutch by Margaret Mathews Hordyk. Pp. xi+130. (New York: Columbia University Press; London: Oxford University Press, 1943.) 10*s*. net.

From 1922 until his death in 1940, Willem Bonger was professor of sociology and criminology in the University of Amsterdam. To psychologists and criminologists he is best known from his "Introduction to Criminology", the outcome of his life's work. In that volume, as in his earlier contributions, he showed himself a keen and critical champion of the view that crime must be regarded as a social or psychological rather than as a medical or biological problem. This was in effect a revolt against the views of the 'anthropological school' of criminology, which, under the leadership of Lombroso and his Italian followers, still dominated the psychology of crime when Bonger first began to write. His last book, on "Race and Crime", deals with what he terms the 'neo-Lombrosian theory'. Mrs. Hordyk received the manuscript only a few days before Holland was invaded, and has produced a most competent and welcome translation.

Dr. Bonger begins by pointing out the highly unscientific way in which the term 'race' has been used, even by anthropologists of repute. An adequate definition, he maintains, ought to imply, not only that the members of the race possess a number of physical and mental characteristics in common, but also that these common characteristics are inherited. Language, the chief criterion of older writers, is not inheritable; and the physical characteristics by which recent anthropologists have attempted to distinguish existing 'races' are in his view "comparatively superficial", and can be but remotely connected with differences in mind or conduct. Moreover, as he observes, when races intermarry, their physical characteristics, such as the determinants of hair and eye colour, may frequently fail to blend; but mental characteristics almost invariably show blending, with a 'normal' rather than a bimodal distribution. Hence groups that may appear to be racially pure when judged by physical criteria may, in point of fact, prove to be highly intermingled when we compare their innate traits of intelligence and temperament. Above all, whether innate or not, "in the psychological sphere, individual differences between members of the same race are so great that differences between races themselves are by comparison small".

The bulk of his book consists in an analysis of recent criminal statistics collected from various countries, and classified according to presumable racial origins. In Europe, for example, during 1927–32, the number of persons convicted of murder and manslaughter per 100,000 of the adult population varied enormously in different countries—from 0·2 in England and Norway to 22·3 in Bulgaria. Broadly speaking, the frequency of such crimes appears lowest in the north-west (though Ireland is a minor exception), somewhat higher in the central areas, higher still in the south, and highest of all in the Balkan and east Baltic areas. At first sight this seems consistent with theories, like that put forward by Kurella and more recently maintained by Martin, to the effect that the Nordic races are freest from crime, the Alpine races nearly as free, the Mediterranean

races decidedly more prone, and the Slavs most liable of all. A more detailed examination, however, shows that, within each country, both the frequency and the nature of the crimes are far more closely related to historical, social, and economic differences than to racial: thus in remote agrarian districts, where material and cultural poverty prevails, crimes against property as well as persons are comparatively common, regardless of racial or national differences; again, in countries where until recently semi-feudal conditions obtained, and particularly where the tradition of private vendetta has survived, homicide is by no means infrequent. The Jewish record for theft, for sexual misdemeanours, and for every type of serious aggressive crime, is everywhere remarkably favourable; on the other hand, commercial crimes are about half as common again among Jews as among other inhabitants of the same country in question. Yet once again these differences are chiefly due to records from urban and commercial areas; and, when local variations are more closely studied, it appears that the offences of the Jews show a marked inclination towards those typical of the areas in which the different Jewish communities are found.

Among immigrants to the United States, the figures for different nationalities at first sight show a general correspondence with those reported from their respective home countries. But this holds true only of the first generation or two: thus, among children of Italian parents who were themselves both born in America, the figures drop practically to the level of native Americans. For Negroes the proportions are nearly three or four times as high as they are for whites; yet, as Dr. Bonger shows by detailed quotation, most American criminologists are agreed that the social and economic conditions under which the Negroes live go far to offer an explanation of the facts observed.

From these and other statistical data, Dr. Bonger finally concludes that differences in racial intelligence and temperament cannot be wholly excluded; but he considers that their influence is remote, indirect, and "sorely exaggerated". Crime, as such, is not inheritable. But there is reason for believing that it "proceeds from instincts common to all men", and that different races may inherit those instincts with differing intensity. Accordingly, although such minor differences in instinctive propensities "have in themselves no necessary connection with crime, still, in certain social circumstances", he holds, "they might impart a stronger anti-social bias to certain members of the population". CYRIL BURT.

FAT METABOLISM

The Metabolism of Fat

(Monographs on Biological Subjects.) By Dr. Ida Smedley-Maclean. Pp. vi+104. (London: Methuen and Co., Ltd., 1943.) 5*s*. net.

THERE is a considerable lack of comprehensive up-to-date monographs on biochemical topics, and especially on fat metabolism. The present book was intended to fill this gap in the field of fat biochemistry and to provide students, especially those with little or no previous knowledge of the subject, with a short account of the present-day knowledge on fat metabolism. The author deals briefly in seven chapters with the synthesis of fatty acids, the constitution and the role of the unsaturated fatty acids in the organism, the oxidation of fatty acids *in vitro* and *in vivo*, the constitution of lipoids and the transport of fatty acids in the animal body. A list of references and a short subject index conclude the book.

The author was aware of the impossibility of giving a complete survey of the field in so short a space, and has succeeded in many respects in giving a clear picture of the broad outlines of our knowledge on the subject. In a number of instances, however, the highly controversial and far from complete picture of fat metabolism is over-simplified and the gaps in our knowledge are filled with a disproportionately long account of current theories. Thus, for example, the views on the possible mechanism of fatty acid synthesis are expounded at some length, which no doubt gives the reader a simple view of the subject, but one little supported by experimental evidence. Also the treatment of the subject of oxidation of fatty acids does not give a balanced view of the experimental evidence and the numerous theories. In the chapter on fat transport in the animal body considerable stress is laid on the theory of Verzar, although many of his results have not been confirmed by other workers.

There are a few errors in chemical formulæ (pp. 78, 79) and in the indexing of references.

A. KLEINZELLER.

ELECTRONIC THEORY IN CHEMISTRY

Electronic Theory and Chemical Reactions

An Elementary Treatment. By R. W. Stott. Pp. viii+112. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1943.) 6*s*. net.

IN the last two decades, the interpretation of reaction mechanism from the point of view of the electronic theory of valency has advanced apace, and the rapid growth of the original literature on the subject has made it difficult for those not primarily engaged in its furtherance to keep abreast of the developments. To some extent this difficulty has recently been met by the appearance of a number of summarizing articles and a few books. In the booklet under review we have the latest addition to this collection.

In six short chapters entitled "Inorganic Compounds", "Organic Acids and Reactive Hydrogen Atoms", "The Mechanisms of Certain Types of Reactions of Organic Compounds", "The Structure of Benzene and other Aromatic Compounds", "Substitution in the Benzene Nucleus", and "Some Uses of Radio-active and other Isotopes", the author attempts to give a brief sketch of the theory of chemical reactions. This is a formidable task, but, though the treatment is in parts somewhat over-simplified, and is not free from errors, the book will undoubtedly be found useful as an elementary introduction to the subject. It is intended mainly for the use of first-year students, for others who have but limited time for reading, and, possibly, for advanced sixth-form pupils. In his preface the author writes: "If this book stimulates interest in what is an attractive subject, and encourages further reading and investigation, it will have fulfilled the purpose for which it has been written". It is the reviewer's opinion that the book will achieve this object.

E. D. HUGHES.

NEOLITHIC FOREST CLEARANCE

By Dr. H. GODWIN
Botany School, Cambridge

IT is the first approximation of the ecologist to relate the control of distribution of major vegetational types to major climatic types : only later does he advance to consider how human activities have interfered with and complicated the pattern determined in the first place by climate. The same relationship has held for the study of palæo-ecology by the methods of pollen-analysis. We have firmly established the general picture of forest movement across north-west Europe under the compulsion of changing climate, and now comes the phase when for the first time we seek to recognize, by pollen-analysis, the rôle of prehistoric man in changing the natural forest cover of Europe. We are brought to recognize this new phase by a recent publication of Johs. Iverson in the series of the Danish Geological Survey*, on "Land Occupation in Denmark's Stone Age".

Iverson begins with the thesis that Palæolithic and Mesolithic men were hunters and fishers, who modified very little the natural vegetation of the lands they so sparsely occupied, and indeed the application of the term 'forest culture' to the Mesolithic implies that the forest dominated man, and not the other way round. With the introduction of farmer culture to Denmark by the invasion of Neolithic man this state of affairs was radically altered, and Iverson seeks and finds evidence for this change in a striking series of pollen investigations. The dating of this change to the Neolithic period can sometimes be directly established ; but more often it can be recognized from the pollen diagrams themselves. It is already well known that the Neolithic in Denmark falls in the middle of the oak-forest period in which oak, elm, and the linden together formed the high forest, with alder and birch in the wetter places and pine and birch in the drier. Iverson points out that pollen of the Ulmus (elm) in the middle of the oak period shows a conspicuous and consistent fall from uniform high to uniform low values. He has, by very laborious counts, shown that the far less frequent pollen of the ivy (*Hedera helix*) shows a very similar decrease at the same time, while the pollen of ash (Fraxinus) increases. This diminution in abundance of such a strongly Atlantic species as the ivy is considered by him to indicate the climatic change from the so-called 'Atlantic' to the 'Sub-boreal' period, a change agreed to fall very near the opening of the Neolithic in this part of Europe. There is no doubt that the fossil elm pollen in Britain gives every sign of coming from a tree with preference for an oceanic climate, and the sudden diminution of its frequency has been already recognized here, as in other parts of north-western Europe, as a trustworthy horizon.

Iverson now points out that in many Danish pollen diagrams, just above this clear climatically determined horizon, the pollen curves indicate a very sudden and peculiar change in forest composition. This is perhaps best shown at Ordrup Mose, where a layer of charcoal stratified into the marginal nekronmuds of a former lake give evidence of burning, and thus perhaps, indirectly, of human occupation. At this level the elements of the high forest, Quercus, Tilia, Fraxinus and Ulmus, undergo a distinct but temporary decline, while Betula reveals a transitory, Alnus a more lasting increase, in pollen frequency, and at the same time the Corylus (hazel) curve reaches a very pronounced maximum. Iverson assumes that these pollen-floristic changes "express the vegetational developments in a region where land-tilling people have occupied the land and cleared this dense primeval forest with axe and fire". The decline of the high forest tree-pollen curves is due to local destruction; the rise of birch, alder and hazel afterwards is due to the rapid regeneration of these species in cleared areas, partly from stumps and partly by their seeds, which, especially in birch and alder, facilitate quick dispersal.

This interpretation receives support from several directions. First is the actual charcoal layer at Ordrup. Second is the fact that at this level the *absolute* tree-pollen frequencies (per unit surface of prepared slide) fall suddenly to very low values and then slowly recover.

Thirdly, Iverson produces striking evidence from the examination of the non-tree pollen content of the lake deposits. Just above the charcoal layer the sum of the non-tree pollen increases suddenly just as one would expect by his hypothesis, but especial importance is attached to his identifications of the species contributing to this total. It had already been pointed out by Firbas that the pollen of cultivated cereals could in general be distinguished by its size and associated characters from that of other grasses, and Iverson shows that continuous though low amounts of cereal pollen are represented in the Ordrup profile above the level of sudden oak forest diminution. Along with this there begins a substantial and continuous curve for the pollen of Plantago, the common plantains, of the species *P. major* and *P. lanceolata*, which have always been very strongly associated with human disturbance of natural vegetation. In addition to this the pollen of Artemisia reaches high percentages, and Iverson suggests that this is probably due to *A. vulgaris*, which was a serious weed in Denmark until the practice of deep ploughing became possible. In several bogs of small size Iverson has been able to show the sudden minimum in the oak forest pollen curves, together with the associated rise of anthropochorus plants, forming an episode so "sudden and brief" in the pollen diagram that it can be taken as indicative of the vegetational succession after local occupation by man and only short-lived settlement. In the deposits of larger fiords or lakes the tree-pollen curves show less sudden disturbances, although the 'weed' and cereal pollen begin continuous curves at the usual level. It is reasonable to consider that pollen diagrams from such places reflect a generalized picture of a whole series of forest clearances over a large tract of countryside, and here, no doubt, it is much less easy to attribute the changes in pollen frequency to the single cause of human interference.

Iverson points out that when the initial phase of disturbance is past, the general forest composition shows little sign of permanent alteration until the beginning of the Early Iron Age. This constancy he is inclined to attribute to the type of forest exploitation practised by the Neolithic settlers, and he speculates that they may well have used the clearance fire to provide not only space for the cultivation of cereals, but also areas of rich herbaceous vegetation and tender tree and shrub shoots to serve for cattle grazing. It is recalled that similar employ-

* Landnam i Danmarks Stenalder (Land Occupation in Denmark's Stone Age). By Johs. Iverson. Danmarks Geologiske Undersøgelse II Række. No. 66. Pp. 68+9 plates. (Copenhagen, 1941.)

ment of clearance fires still continues in backward parts of Europe, and that the Danish archæologist G. Hatt had already indicated the probability that it was in use in prehistoric Denmark.

It follows naturally that if we accept the argument of Iverson thus far, we must expect to find that when the 'Sub-atlantic' climatic period began, no less important vegetational changes took place. For at this time not only the swift climatic 'deterioration' occurred, but also the establishment of a new people with iron implements and the permanent regular settlement associated with village culture. In fact, Iverson is able to demonstrate that the pollen diagrams and peat profiles do reflect such changes. There is the extensive water-logging of low-lying land and the formation of aquatic 'precursor' peat with *Scheuchzeria palustris* above the uniform and highly humified Sphagnum-Calluna peat of raised bogs, and there is the considerable extension of Fagus (beech) at the expense of Quercus (oak) in the pollen diagrams. Both these are climatic effects. In addition, there is a progressive forest destruction by human activity which is indicated by a further considerable increase in the pollen of herbaceous plants, and, in the heathy areas, by increase in the pollen of the ling, *Calluna vulgaris*. The pollen diagrams indicate that in the heath region of central Jutland it was not until the Early Iron Age that great and continuous areas of heath were formed, although some heath was doubtless produced by Neolithic and Bronze Age clearance, and even in Pre-neolithic times the woodlands were much more open than those on the heavier soils.

Iverson's most stimulating piece of research emphasizes what was already dimly recognized, that an *ecological* approach to the interpretation of the results of pollen-analysis is logical and profitable, and indicates that the pollen-analysis method has proved its flexibility by application to yet another aspect of post-glacial history. We may now look for confirmatory results in this special field from many other parts of Europe.

ANCIENT ASTROLOGY

By JOSHUA C. GREGORY
University of Leeds

IN A.D. 1605 Sir Francis Bacon appended to the "Advancement of Learning" some prescriptions for posterity. These contain an injunction to construct "A Just Astrology". Bacon had previously assessed the then condition of this science in his main text. Like alchemy, astrology had a noble aim; like alchemy again, it had been more imaginative than rational; and, once more like alchemy, it needed the corrective and the purge. Astrology, as Bacon conceives it, is central and fundamental, for he defines it as "the real effects of the celestial bodies upon the terrestrial". This includes the action of the sun on the earth: without which there would be no astrology, because there would be no astrologers.

Posterity has obeyed Bacon in one way by sharpening and deepening its sense of absolute dependence on the sun. The cosmic course has made continuing human life possible by isolating the humble solar system in the vastness of space, and by placing the modest earth, with all its appropriate conditions, in nice adjustment to the solar rays. If the sun cooled down, mankind would freeze out; if it exploded into a fierce burst of radiation, the earth would become a great crematorium. If an invading body tore the earth too far away from the sun, or the sun from the earth, men would freeze; if it drove the earth and sun too near, or collided with the sun to make too fierce a furnace, men would burn. Invaders have far to come to reach an earth 4½ light-years away from the nearest star and very remote from the galactic depths. Though the importance of the sun is too obvious to be missed, the ancient mind probably grasped man's absolute dependence on it less completely than modern astronomy.

Plato's "Timæos" is very preoccupied with the sun as a measure of time, a revealer of number and a teacher of arithmetic. The moon, the planets and their motions share in the lessons. The Platonic Socrates, however, gives the sun its due in the "Republic" as the author of visibility, generation, nourishment and growth, though the sun itself is not generated. Modern astronomy, or, in Bacon's sense, astrology, does not confine celestial actions to the sun. The moon pulls more than the sun at the tides to produce their effects—on navigation, for example, or on some marine organisms. The cosmic rays still have their enigmas. If they do come partly from the stars and do act on genes, modern astrology will recognize some stellar influence. According to Aristotle's "De Cælo", the moving celestial bodies emit heat and light by rubbing against the air. The "Meteorologica" supplements this. Neither the moon nor any star gives out much heat: the moon is near, but too slow, and the star is rapid but too far off. The sun is both swift enough and near enough to warm the earth well. Though the two passages claim little for non-solar influences, they do indicate how readily celestial bodies could be presumed to affect the earth. The ancient mind did, in fact, as ancient astrology shows, very liberally supplement the celestial action of the sun.

Greek science, including astronomy, began on May 28, 585 B.C.: Thales predicted an eclipse of the sun for that day, and Nature obligingly darkened a battle between the Lydians and the Medes. This statement is too dramatic to be literally true, but Thales and the eclipse conveniently date the still accepted origin of Greek science (and philosophy) in the sixth century B.C. Thales was lucky, as Heath notes, for the Babylonian period on which he depended is less reliable for solar than for lunar eclipses. In 2159 B.C. the Chinese astronomers Hi and Ho were unlucky. Thales predicted an eclipse and gained prestige; Hi and Ho did not predict an eclipse and were executed.

From Thales the current of science runs to one great decisive century of thought—the fourth century B.C., the century dominated by Plato and Aristotle. In drastic summary, and so far as possible from the scientific point of view, a mathematical tradition runs from the anti-experimental Plato and a second trend of thought runs from Aristotle. Mathematics had its hand in astronomy and astrology. Science reaches an acme in the third century. In mathematics it includes Euclid and Archimedes; in astronomy it includes Eratosthenes, who measured the earth's diameter very accurately, and Aristarchos, who anticipated the Copernican theory. Herophilos founded scientific anatomy and Erasistratos founded scientific physiology. Then science begins to run into relative, though recognizable, termini. In the first century B.C. Lucretius stores the fundamentals of atomism in his famous poem, "De Rerum Natura",

for still far future centuries. Fortune has been capricious towards atomic theories. When the atoms tried to enter physics they were soon defeated ; their more determined attempt to enter medicine was finally foiled by Galen at the end of the great Greco-Roman period in A.D. 200. Many centuries after, the atoms became an extraordinarily fertile concept—one of the most fertile, perhaps the most fertile, of all physical theories.

Science is considerably consolidated from the first century B.C. to the first century A.D. in such writings as those of Cicero, Vitruvius and Plutarch. In the first and second centuries A.D. science drops into four relatively permanent and authoritative consolidations. In A.D. 77 Pliny pours a miscellany of facts, presumed facts and ideas into his "Natural History"—that "immense register", as Gibbon says, in which were "deposited the discoveries, the arts and the errors of mankind". It had its own authority and its own influence over future centuries, though it does state that elephants worship the stars.

Clarke, in his translation of Seneca's "Quæstiones Naturales", under the title "Physical Science in the Time of Nero", calls it the last deliverance of the classical world on physical speculation. Seneca authoritatively consolidates physics for coming centuries.

Singer, in "A Short History of Science", heads his chapter on the divorce of science and philosophy, from 300 B.C. to A.D. 200, "The Failure of Nerve". This expresses the decline of science rather oddly, for Ptolemy and Galen, in the second century A.D., are experimental and have at least a notion of the nature of scientific hypothesis. If the "Optics" as now known is as Ptolemy wrote it—and Thorndike thinks it is so substantially—it represents the most remarkable experimental research in antiquity. The oddness seems less when a candle is seen to flicker up before it dies. Science has before it the long path through the Middle Ages to the decisive seventeenth century. Ptolemy's consolidation of astronomy remains authoritative until Copernicus and Kepler in the sixteenth and seventeenth centuries. Galen's great biological, anatomical and medical synthesis, which includes his own inductive and experimental inquiries, remains authoritative until the sixteenth-century Vesalius. Seneca, the neo-Stoic, Ptolemy, the mathematician and astronomer, Galen, the physician—each consolidates the results of science in his own way. They have one belief in common—the control of human destiny by the planets and the stars.

In 1609 Kepler introduced the elliptical planetary orbit. This decisive step effectively made the transition from the geocentric Ptolemaic system to the heliocentric Copernican astronomy. Astrology had persisted during fourteen centuries after Galen, for Kepler still checked his own horoscope on his own life.

The horoscope displays the dispositions of the celestial bodies, or relevant celestial bodies, at a particular moment. When Johnson accused Dryden of "great confidence in the prognostications of judicial astrology", he meant that Dryden believed in the casting of nativities and even calculated them himself. Such *judicial* astrology casts the horoscope of birth or conception to determine the destiny of the born. Webster's "New International Dictionary" (1914) distinguishes *judicial* astrology, which predicts the destinies of individuals or nations, from *natural* astrology, which predicts natural events. Bacon included horoscope astrology in his purge. Seneca and Galen include the horoscope in their doctrine, though Galen's astrology is largely medical. Ptolemy describes the philosophy of horoscope astrology.

Nothing is too strange or incredible for some philosopher to believe—so judged the young Descartes when he was at college. Men have believed very many strange things, and perhaps they still do. A universe created as a compact mass and expanding from its terrific initial concentration may be among them. A modern cosmologist fortifies the doctrine by mathematics and dates the primal pack so far as 2×10^9 years ago. Horoscope astrology, however, is too significant a phase of thought to be eyed merely as a curious error.

Human thought has been fated to tread a predestined path, as an acorn steps its way to the oak. This is a good working principle if taken widely, if used in Sir Thomas Browne's "soft and flexible sense" and if not made a fetish by reason. The mind seems to have been committed to a magical phase, for example, though not to every magical detail. In any event, the route to such insight as has been attained has been through many illusions and errors. This is true of astronomy and astrology. The historian should consult the acorn and be wise, for the phases of thought should be contemplated as acorns and not merely chided for not being oaks. The future historian will probably see many acorns in the twentieth century—some promising, some sterile. Discarded hypotheses strew the devious path of science, and many astrological notions lie among them. These notions have at least one value still, for they give glimpses of the mind at work. Analysis conveniently derives them doubly from the concepts of their time and from impressions made by natural phenomena, though the two are ultimately and intimately connected.

Most men accept happiness as the chief good, though they disagree about its nature. This statement from the opening pages of Aristotle's "Ethics" has a modern ring. An otherwise well-educated man who knows nothing of Greek thought might conceivably mistake the "Ethics" or "Rhetoric" or "Poetics" of Aristotle for a modern work. This peculiarly educated man is a legitimate expository expedient to point a contrast. "A man's language ought to be easy for another to read, pronounce and point" : this sentence from the "Rhetoric" is modern enough. So is the notion adopted from Agathon in the "Poetics" : it is probable that many improbable things will happen. The supposititious reader would never mistake Aristotle's "De Cælo" or "Meteorologica" for a modern work. Intelligent stars, the roles of the four elements, easily credited spontaneous generations, for example, and the whole range of physical ideas date the two works relentlessly. Physics, in one very real sense, is the most fundamental science. It is very fundamental if men emerged from the cosmic course among the ephemeridæ of the universe. Greek philosophies almost invariably had their physics, and the earlier philosophies, at least, if they were assessed for the first time to-day, would probably be called philosophies of physics, as Eddington calls his work "The Philosophy of Physical Science". The physical world is more alien to us, in a recognizable sense, than the more domestic circle of human experience. Aristotle can deal with courage in the "Ethics", for example, or with the qualities of metaphors in the "Poetics" and the "Rhetoric", with more immediate success than he can secure in physics. A defective physics is one important item in the conceptual system that

promoted early astrologies. Greek philosophies regularly had their astronomies and astrologies.

Prospero's isle seemed to Caliban to be full of noises; the universe seemed to Seneca and Ptolemy to be pervaded by forces. The four traditional powers—dry, moist and, eminently, hot and cold—dynamically inter-connect the earth and the celestial bodies in the Ptolemaic universe. The heavens also send a force on to the earth. In Seneca's cosmology lightning has its subtle divine power, underground forces convert air into water, and a mighty force pervades Nature. Seneca's *force* is constantly modelled on the air, and the air itself, in various forms, is for him virtually a ubiquitous agent. It is the greatest of all powers for it kindles fire. The air drives trees up, holds our bodies together and stirs our souls, themselves a kind of air; a robust air keeps the earth compact and a fresh vital air from the earth supports life. The breath of the earth sustains the sun, the stars and the whole heavenly concourse. The inverted astrology of this statement contains a vivid sense of pervading cosmic forces. A crude physics assists this sense, and the cosmic spread of air provides an astrological agent.

Britain is great through the muscles of her sons, beef feeds the muscles, clover nourishes the cattle and bees fertilize the clover. Field-mice would destroy the bees, but cats kill the mice and old maids make Britain because they keep the cats. An item in the Hippocratic writings, whenever it was inserted, expresses the interconnexion of things less facetiously: if any one thing perished, all things would vanish. Every event, says Seneca, is a sign of an event to come. The sense of interconnected events is vivid in Stoicism.

Einstein's "cosmic religious feeling", stirred by the "sense of universal causation" and "the harmony of natural law", has its ancient analogue in the sense of the divine. In the "Apology" Socrates affirms a universal belief in the godhead of the sun or moon. Anaxagoras had been indicted because he called the sun a red-hot stone and the moon an earthy mass. In Plato's "Laws" the Athenian Stranger claims divinity for the sun, moon and stars against the earth and stones of mischievous philosophers. In the "Timæos" the stars and the planets are created gods; for Aristotle the stars, made of purest æther, are intelligent and divine. The divinity of the celestial bodies, as gods or godlike, persisted from Babylonian and Egyptian lore through the Greco-Roman tradition far into the Christian era. As Thorndike notes, Seneca studying the natural forces suggests the worshipper in the temple.

The Stoic Fate, however finally assessed, embodies two compelling concepts. It contains the belief in determinate causal connexions and natural law that emerged in Greek thought as the working faith of science. It contains also the sense of purpose, or aiming at ends, from which the Greek, or Greco-Roman, estimate of *cause* seldom got far away. Atomism had affronted this sense of the purposive too much to be welcomed for its sense of strict causality when Galen gave it the *coup de grâce* in medicine.

The ancient universe is physically misconstrued, pervaded by forces, interconnected throughout by determinately connected causes, a realm of natural law, a domain of sympathies or antipathies, suffused with purpose and impressively divine. "Astrology fell upon the Hellenistic mind as a new disease falls upon a remote island people": so writes Sir Gilbert Murray. Men realized truly that astronomy must finally achieve an astrology of some sort, though they tried to achieve it too quickly by inadequate means—this is a fair précis of a paragraph from Coleridge. The stars probably do mean something, John Selden thought in the seventeenth century, but astrologers cannot get at them to determine what. The stars *do* mean something and something can be known about the *what*—so thought Seneca, Ptolemy, Galen and many ancients.

Thucydides records how a lunar eclipse kept an Athenian host in port until the twenty-seven days prescribed by the soothsayers had passed. Samuel Pepys looked more imperturbably on the unfortunate comet that had lost its tail than many other eyes had looked on other comets. Eclipses, comets and many other astronomical or meteorological items took a hand in promoting astrologies. One item, in particular, had as many hands in the matter as Briareus. Pepys was recompensed for his toilsome studies of the moon's motions when it lighted him home on a dark night. Tiberius hoped to save his shorn poll from baldness by having his hair cut as the moon waxed. The belief in lunar control, the response of things or events to the lunar wax by increase and to the lunar wane by decrease, began early, extended to innumerable items and persisted pertinaciously.

Aristotle refers to the presumed connexion between moon and menstruation which runs through the tradition. In Galen the lunar phases still rule conception, birth and the "beginnings of actions": a belief rich in astrological possibilities. The innocent indifferent moon, which presumably knows nothing of such speculations, has been suspected of setting the whole astrological system going—horoscopes and all.

Neither Pythias, in the later fourth century B.C., when he correlated the lunar phases with the tides, nor Posidionius, about the first century B.C., when he recognized the combined tidal action of the moon and sun, drove the moon out of horoscope astrology. The moon hauls the tides; according to Galen it changes the air. If polluted air spreads disease, and the Hippocratic "Breaths" refers both life and sickness to the air, it may be infected from the skies. Pestilence can come from the sky if atoms from the great beyond can derange the air, as Lucretius sings, or atoms from the celestial bodies can spread epidemics, as Democritus affirms. Though the atomists are condemned by Galen for refusing astrology, they can accept widespread celestial actions by invading atoms.

In Aristotle and Galen the air connects the earth with the heavenly bodies. Under "Astronomy" in James's "A Medicinal Dictionary" (A.D. 1743), the sun, moon, planets and stars are said to act on terrestrial bodies through the æther and the atmosphere: even the distant stars affect human bodies by disturbing the air. Astrology, horoscopic or non-horoscopic, constantly trusts in the moon's power and relies on the astrological agency of air.

The astrological tradition is perceptible in the "Timæos", in the terrors sent and intimations given to expert calculators by the combined motions of the planets. The horoscope invades Stoicism, Rome and Greco-Roman thought during the second and first centuries B.C. Two dissentients mark the invasion: Panætios the Stoic in the second century and Cicero in the first. The signs of the zodiac connect modern astronomy with astrology and with

its origin, for they admittedly come from Babylonia. The tradition insistently refers the origin of astrology to the Chaldæans.

Berossos the Babylonian wrote a history of his country in the third century B.C. As the tradition appears in Vitruvius, for example, the Chaldæans cast nativities, Berossos presses their astrology on his school at Cos, Antipater and Archinapolos alter the horoscope from birth to conception, and astrology grips Greco-Roman thought. The encyclopædic history of Diodoros, about 30 B.C., describes the theory and method of the Chaldæans: the events of the heavens intimate the thoughts of the gods, so the stars were observed for many ages. So astrological theory promoted astronomy. The Babylonians are said to have checked horoscopes on the recorded lives of Babylonian boys. Even if they did this for less than the 470 years of one more moderate estimate, their inductive effort, if not their deductive doctrine, must be reckoned as scientific righteousness.

Did all the Romans who fell at Cannæ have the same horoscope? Cicero's question sounds pertinent. When the birth of Firminus was nigh, a slave-woman of his father's house was also near her delivery. Messengers were posted in either house to run to the other with news of each birth. The two messengers met so exactly in the middle of the way that the two births must have happened at precisely the same instant. Yet, St. Augustine further records, Firminus was born to increasing riches and honours, but the slave-born child was born to continued slavery. Cicero and St. Augustine argue inversely against the horoscope: Cicero from one fate and different horoscopes; St. Augustine from one horoscope and different fates. Either argument might be valid if, and only if, the disposition of the heavenly bodies at birth is the singly decisive decider of destiny. Ptolemy denies that it is singly decisive.

An anticipatory reply to St. Augustine can be shortly constructed from Ptolemy's "Tetrabiblos". Famines, pestilences, wars and the like, which affect large areas, whole peoples and cities, are more surely predicted than single human actions. The effect of the stars on the human individual is conditioned by his nationality, his country and his domicile. It is also conditioned by his period, for time varies the celestial actions. Firminus and the slave were born at the same time, in the same city and among the same people, but under different social conditions. They were also differently educated. Ptolemy disclaims an astrological narrowness if previous astrologers had ignored place, weather and heredity, as Cicero, in the "De Divinatione", says they did.

Ptolemy insists on the complexities of the celestial dispositions, on the manifold causes acting on the individual, and on the present imperfections of astrology. Predictions often fail because the science is immature, but frequent shipwrecks do not destroy the art of navigation. Ptolemy's frank admission of predictive failures contrasts with the bold statement by Diodoros that when the Chaldæans prophesied about kings they were always right.

Ptolemy repudiates impostors. He claims that the science has present value in spite of imperfections or failures, and that time will increase the value. Astrology is not useless because the stars decree inevitably: if they do cause a disease, a drug may cure it. Ptolemy manifests a recognizably scientific temper in handling a now discredited hypothesis.

Scientific inquiry is not incompatible with cosmic purposes, for Galen inquired how purposive Nature purposes. It is not incompatible with Providential ordering, for Galen inquired into the natural law through which God works, though the existence of God did not seem to him to be proved. If the stars do operate divine purposes, astrology can still have its operative scheme, as Galen had his attractive forces. A force radiated from the stars is central in early astrological doctrine—Cicero notes how the Chaldæans lodge it in the zodiac, Ptolemy speaks of the force diffused from the heavens on terrestrial things, and according to Galen "we receive the force of all the stars above". This force is variously affected by the sun, moon and planets according to their positions, conjunctions and relations to the signs of the zodiac. Other powers may co-operate, such as hot or cold, and an eye is often kept on the astrological agency of the air.

The moon is constantly prominent in the astrological versions. It has no more power than the other planets, Galen explains, but it is nearer. The Chaldæans, Cicero tells us, were careful to note the condition of the moon and its conjunctions with the stars at the moment of birth. The moon is usually peculiarly important in astrological theory, Thorndike notes, and more distant planets often act on the earth through it. It is quite reasonably, even if unjustifiably, suspected of inflicting genethlialogy, the science of nativities, upon many minds through many centuries.

The Chaldæan type of astrology is one hypothesis which marks the route of science. It seems to be an intelligible consequence of one phase in human thinking, and perhaps more so because man very earnestly wants to know what will happen.

PRE-NEANDERTHAL MAN IN THE CRIMEA

By Sir ARTHUR KEITH, F.R.S.

In 1925 there appeared an annotation in *L'Anthropologie*[1] directing attention to the discoveries of ancient man and of his cultures then being made in the Crimea by G. A. Bonč-Osmolovskij, conservator of the Russian Museum in Leningrad. The chief site of these discoveries was the grotto or rock-shelter of Kiik-Koba, situated in the foothills of the Yaila Mountains, which run from Sebastopol towards the Kerch Straits. In the deepest and oldest stratum of the grotto were found fossil remains of part of a human skeleton; these were reported to be Neanderthal in character; they were examined by the late Dr. Marcelin Boule, who confirmed this diagnosis. The Crimea was then the most easterly point from which Neanderthal man had been reported. Students of early man were deeply interested in the discoveries reported by their Russian colleague and have eagerly awaited his full report—so far in vain. Recently my interest in Kiik-Koba was heightened by an article published in *Man* by Prof. Gordon Childe[2], in which the strata of the grotto are identified as similar in age and in sequence to those which yielded the fossil men of Mount Carmel—the subject of a report published by Dr. Theodore McCown and myself in 1939[3]. In February of the present year (1944) a pleasant surprise awaited me; on opening a parcel bearing the Moscow postmark, I found within a volume entitled

—in the French translation kindly supplied by the author—"L'Homme fossile de la Grotte de Kiik-Koba (Crimée)". I found it to be Part 2 of the "Paleolit Kryma"*, published in Moscow in 1941. Part 1, which gives an account of the strata of the grotto and of their contents, was published in 1940. Inside the cover of the book which came to me so unexpectedly, the author has written an inscription in English; it is signed G. A. Bonč-Osmolovskij and dated December 10, 1942. Considering the obstacles which lay between the author and myself, the wonder is, not that the book took more than a year to reach me, but that it ever arrived.

As I came to know the contents of this book, which was made possible for me by the author's full résumé in French and by his supplying the numerous illustrations with legends in that language, I saw why we had had to wait so long for this report. Part 2 consists of 171 closely printed pages of Russian text, all of it devoted to one part of the Kiik-Kobian man—the hand. Men of the early Pleistocene are represented by specimens from Java, China, Heidelberg and Piltdown; the later Pleistocene has given us a score or more of fossil Neanthalians, all from Mousterian sites, but of the men of the middle Pleistocene we know very little. It was the realization of this blank in our knowledge that made the author resolve to squeeze every item of information from the fossil bones of the Kiik-Kobian hand to an extent that has never before been attempted. He had at his disposal only two bones of the carpus (trapezium, trapezoid); two of the ten metacarpi (those of the thumb and ring finger); and fourteen phalanges of the fingers. Some of the bones belong to the right hand and some to the left; by using mirror-images of the left bones he was able to incorporate them into a reconstruction of the Kiik-Kobian right hand. In the course of doing this he observed that those of the right were slightly the larger, pointing to right-handedness. To give his inferences a wide foundation, the author has extended his inquiries to the hands of modern man and of apes, and to the embryology of the hand of man and of apes; in short, he has constructed a new branch of inferential anatomy. He set out to give a description of a mid-Pleistocene European and ended by giving not only such a description but also what amounts to a treatise on the evolution of the human hand.

Kiik-Kobian man belongs to an age which precedes that which marks the appearance of Neanderthal man in Western Europe; he represents the folk of the upper or later Acheulean period of stone-culture. The only other site which had yielded fossil remains of Acheulean man, so far as M. Bonč-Osmolovskij could learn, was the Tabūn cave of Mount Carmel excavated (1929–34) by an expedition sent out by the British School of Archæology in Jerusalem and the American School of Prehistoric Research under the direction of Prof. Dorothy Garrod[4]. At Tabūn the superimposed cave deposits reached the enormous depth of 80 ft.; as at Kiik-Koba, the bottom stratum was of the remote palæolithic age known as Tayacian; in this ancient stratum Kiik-Kobian man had been buried—the oldest human grave known to us as yet. Over the bottom stratum, at Tabūn as at Kiik-Koba, come deposits of the later Acheulean, having a thickness of 16 ft. at Tabūn. Then, at Tabūn but not at Kiik-Koba, there follow strata—40 ft. of them—laid down during the period of Mousterian culture. The company of fossil Carmelites described by Dr. McCown and myself came from the deeper Mousterian layers. The Acheulean deposits yielded us only two fossil fragments—the greater part of the shaft of a femur and a worn lower molar tooth. We estimated the original length of the Tabūn femur, and from that gave the Tabūn Acheulean man a stature of 1·656 m. (5ft. 5in.); the Kiik-Kobian man is estimated (from the length of his tibia) to have been about 1·59 m. (5ft. 2·6in.). On comparing the femur and molar from the Acheulean deposits with the corresponding parts of the Mousterian Carmelites, we found a degree of correspondence that led us to regard the Acheuleans of Tabūn as probably ancestral to the Carmelites. The cultural evidence, however, is against our supposition, for Prof. Garrod noted a definite change in the type of stone implement on passing from the Acheulean to the Mousterian strata.

There was no femur, no molar tooth, found at Kiik-Koba with which we might compare our Tabūn specimens. When, however, we compare the Crimean hand-bones with those of the Mousterian Carmelites, we find them sharing in certain features which are also present in the hand-bones of Neanderthal man, but not in those of modern man. But in their massiveness and in their ruggedness the hand-bones of Kiik-Kobian man show a primitive characterization. He may well have been, as Bonč-Osmolovskij claims, ancestral to the Neanderthalians of Europe. Heidelberg man, who is known only by his lower jaw, has also a claim to be on the Neanderthalian ancestral line; a worn lower incisor, the only tooth found at Kiik-Koba, would be in place in a Heidelbergian mandible.

His painstaking methods have permitted M. Bonč-Osmolovskij to unfold a strange act of vandalism on the part of the Acheulean cave-men of Kiik-Koba. Not only had a man been buried in the bottom stratum, but also a child of about one year in age had been laid to rest near him, with its head directed towards his. Afterwards, for some unknown reason, the Acheuleans excavated and threw out that part of the floor of their cave which contained the graves, leaving *in situ* only the feet, right leg bones and parts of both hands of the man and those parts of the child which lie below the waist. Of the missing parts of the two individuals, only a worn lower incisor was recovered.

The author has my warm approval when he names this Crimean fossil type simply Kiik-Kobian man—*Homo kiik-kobiensis*. Future discoveries will reveal his exact place in the scheme of human evolution. But I doubt if my British colleagues will agree with him in the place he assigns to his fossil type in the scale of time. He places it, not in the last great interglacial period—the Riss-Würm—but towards the end of the preceding interglacial, the Mindel-Riss. Miss D. M. A. Bate[5] has reported on the fossil fauna from Tabūn; she found that the chief change took place, not at the end of the Acheulean period, but towards the end of the Mousterian. Consequently the Acheulean as well as the Mousterian cultures at Tabūn are regarded as lying in the Riss-Würm interglacial.

Bonč-Osmolovskij gives the Kiik-Kobian the short, thick and squat hand of a labouring man; he was a labourer who used stone tools. He quotes Engels to

* Paleolit Kryma. By G. A. Bonč-Osmolovskij. Vypusk 2: Kist' iskopaemogo čeloveka iz grota Kiik-Koba. (With a résumé in French.) Pp. 172+8 plates. (Moscow and Leningrad: Akademie Nauk SSSR, 1941.) 16.50 roubles.

the effect that "la main n'est pas seulement un organ de travail; elle en est aussi un produit". Our Carmelites also laboured with stone tools, but their hands had the shape and proportions still to be seen in native races. The author regards the squat, plate-like hand and foot which appear in the embryonic stage of man and ape as the original primate type; Kiik-Kobian man, he believes, has retained this type. He seeks to explain the retention of the primitive form of hand in man by supposing that man never was a tree climber, as his anthropoid cousins became, but that he was evolved in treeless surroundings, such as those which now exist in South Africa. He follows with a lively interest the history of the fossil South African anthropoids as it is being unfolded by Dr. Robert Broom and Prof. Raymond Dart, and expects to find support for his theory from that source. I, on the other hand, regard the embryonic hand of man and ape as representative of a structure which never had existence outside the womb; the embryonic hand depicts a stage in development, not in evolution. I seek to account for man's form of hand by supposing that even in the arboreal stage of his evolution, when he was a climbing animal, his lower extremities and feet were his chief means of support; his hands were never modified to form hooks, as in his hand-clinging anthropoid cousins[6].

My Russian colleague and I seem fated to construe prehistoric facts in a contrary manner. To him the fossil men of Java, of Peking, of Kiik-Koba, of Neanderthal, represent an ascending series which culminates, without a break, in *Homo sapiens*. For me, these pleistocene types represent separate evolutionary products, each being at a different stage of evolution. Bagehot showed a remarkable prescience when he declared (1869) that ancient races of mankind were "parish races". A transitional Neanderthal-Modern type has been discovered in Palestine but never in Europe. In Java, the early Pithecanthropoid is now linked to a later Australoid form by a series of fossil intermediates. The English contemporary of the Kiik-Kobians—the man whose skull was discovered deep in the Acheulean gravels at Swanscombe in the Thames valley by Mr. Alvan Marston in 1935[7], was not at all Kiik-Kobian in type. So far as his characters can be made out, they link him, not to the Neanderthalians, but to the earliest known fossil type in Britain—Piltdown man[8]. Our evidence as it now stands is very imperfect, but such as it is, it entitles us to assume that the British peninsula of Europe had, in earliest pleistocene times, its own type of humanity.

Although my interpretations clash with those of my Russian colleague at several points, that does not blind me to the fact that he has made a contribution to our knowledge of the highest importance; he has enriched our modes of anthropological inquiry, as well as our armoury of fact. Students of human evolution await the monographs which will complete his Kiik-Kobian studies with a lively interest.

OBITUARIES

Prof. L. R. Wilberforce

Lionel Robert Wilberforce, eldest son of Edward Wilberforce, Master of the Supreme Court, and great-grandson of William Wilberforce, the emancipator, was born at Munich on April 18, 1861. After receiving his early education at the London International College, Isleworth, he became a foundation scholar of Trinity College, Cambridge. He graduated as thirteenth Wrangler and obtained a first class in the Natural Science Tripos.

In 1887 Wilberforce was appointed assistant demonstrator to Sir J. J. Thomson at Cambridge, becoming demonstrator in 1890 and University lecturer in physics in 1900. In the same year he succeeded Sir Oliver Lodge as professor of physics in the University of Liverpool, where he was at once faced with the planning of a new laboratory. This work was so well done that, except for limitations of space, it has satisfied most of the needs of present-day workers. It was in this laboratory that Barkla discovered the characteristic X-ray radiations of the elements. Some years previous to this, Wilberforce had suggested the now well-known method of investigating the polarization of X-rays, which in the able hands of Barkla provided the first real evidence of the undulatory nature of X-rays.

Judged by modern standards, the number of scientific papers published by Wilberforce is not large. His interests covered almost the whole range of classical physics. In his Cambridge days he wrote on surface tension, viscosity, the vibration of loaded spiral springs and miscellaneous electrical topics. A fascinating product of his work on springs is the comparatively little-known Wilberforce spring which admirably illustrates the periodic transfer of energy from translation to rotation. Wilberforce was a strong advocate of the kinematic design of instruments. His kinematic clamps and boss head, which he described in a lecture to the Physical Society in 1932, have given much satisfaction in many laboratories. In his later years, Wilberforce became interested in the subject of electrical units, and was in frequent correspondence with the late Sir Richard Glazebrook. Arising from this were two penetrating papers on magnetism in the *Proceedings of the Physical Society* of 1933 and 1934.

Wilberforce was an excellent teacher. He had a thorough understanding of all types of students. For the beginner he wrote, with Fitzpatrick, "A Laboratory Note Book of Elementary Practical Physics". That he had a clear perception of the difficulties involved in the teaching of physics is brought out in the interesting chapter he contributed to "A History of the Cavendish Laboratory". He took great pains to make physics attractive to his students. His lectures were almost lavishly illustrated with experiments, the demonstration of which gave him much delight. In describing physical phenomena—always in his own way—he seemed to prefer words to symbols. It is, however, as a popular lecturer that he will be most widely remembered. He devoted an extraordinary amount of time to the perfection of his lecture demonstrations. He was quite early in the field with an ingeniously constructed wave model and ripple tank which he exhibited on many occasions.

Wilberforce excelled as an administrator. His courtesy, ready wit, genial personality and clarity

of outlook were important factors in making him a most successful chairman of the many university committees on which he served. His work as acting vice-chancellor of the University of Liverpool for one session was much appreciated.

Wilberforce vacated the Lyon Jones chair of physics in 1935 in full vigour. He continued to serve on the committee of the Liverpool Maternity Hospital, of which he had been vice-president for more than twenty years, and on the committee of the Liverpool Radium Institute, besides taking an active interest in church work.

No account of Wilberforce would be complete without reference to his mountaineering activities and his great skill as a skater, which he maintained almost to the time of his death in his eighty-third year. R. W. Roberts.

Sir Thomas Ranken Lyle, F.R.S.

Former students of the University of Melbourne in all parts of the world will be sorry at the death in Melbourne of Sir Thomas Ranken Lyle, at the age of eighty-three. Lyle came from Dublin, after an academic career of distinction (enhanced by three years of playing Rugby for Ireland), to the Melbourne chair of natural philosophy in 1889, when the University was in its thirty-sixth year and he in his thirtieth; he held the professorship for more than a quarter-century, and thereafter continued to give valuable services to the State of Victoria until a few years ago.

In the school of physics Lyle had at first much to build up—though on a sound foundation—and he very soon became one of the vigorous group of young professors who in the ensuing years did great work in advancing the University both internally and by reputation. Lyle's direct contributions to physics, especially in the principles of current generation in dynamos, were recognized in 1912 by the fellowship of the Royal Society. His knighthood came in 1922.

In the more elementary parts of his teaching, to students of engineering and medicine as well as science, Lyle imparted even to backward members of a class solid realities and conceptions which endured. For the better students, and in senior work, he laid very fine foundations indeed. No one who was in Lyle's classes could forget his firm good-humour, his benign tolerance of the mathematical weakling. He himself was a strong mathematician, though his first-year men—confusing arithmetic with mathematics—were apt to watch hopefully for the contest for the right result between any of his admirable lecture-bench experiments and his impatient manipulation of a Fuller's slide-rule in working them out. As befitted a good experimenter, any error was always debited to the slide rule. But no student took liberties with Lyle; they all felt too much respect and affection towards him for that. He did not seek this: he received it. His strong and honourable common sense, his shrewdness that stooped to nothing petty, the reserves of his judgment and its cogency when he did give it utterance, helped to make him a force in the whole University and, coupled with a geniality brought from his native land, made him a friend for life of its other best men.

Retiring fairly early from his chair, Lyle was called upon to give advice to the State on educational questions and, especially, on large technical developments: first as chairman of the Electricity Commission of Victoria and then for nearly twenty years more a member, he did very important public work which, with his impress on the University, has had effects which will endure.

Lyle married Clare Millear in 1892; and their family have made high places of their own in Australian affairs. J. I. O. Masson.

Mr. S. E. Winbolt

Archæology has lost a keen worker by the death, at the age of seventy-six, of Samuel Edward Winbolt. Educated at Christ's Hospital and at Corpus Christi College, Oxford, where he took high classical honours, he returned to Christ's Hospital as a master. There he published some educational editions of the classics and other works on history and English literature. His classical training turned his attention naturally to Roman and kindred archæology, to which he devoted himself upon his retirement.

Winbolt's most important work was the excavation of the large Roman villa at Folkestone, published in book form, "Roman Folkestone", in 1925; the smaller villa at Southwick, Sussex, owned by the Sussex Archæological Trust; the posting stations on Stane Street and other detailed investigations upon this Roman road, published recently in "With a Spade on Stane Street", which will be the standard authority on this road; a series of camps of the Early Iron Age in the Weald ranging from Tonbridge to Hascombe; and the rediscovery of the sites of the important local medieval glass industry at Chiddingfold, near Horsham, published in book form, "Wealden Glass" (Combridge, Hove), in 1933.

Winbolt contributed the Romano-British portion, an important collection of material of the volume on Sussex, in the Victoria County History. He prepared some attractive guides for Bell's county series, including Sussex, Kent, Devon, Somerset and others. He had a gift for the popular exposition of archæology and one of his last works was a Pelican book on prehistoric Britain, "Britain B.C.". A most helpful correspondent, he had great charm of manner, and the important knack of encouraging beginners and young helpers in archæology. I. D. Margary.

Prof. L. S. Palmer

Prof. L. S. Palmer, chief in the Division of Agricultural Biochemistry of the Department of Agriculture at the University of Minnesota, died on March 8 at the age of fifty-six. Dr. Palmer had been at the University of Minnesota since 1919 and became head of the division at University Farm a year ago, succeeding the late Dr. Ross A. Gortner. More than thirty years of research and teaching at the Universities of Missouri and Minnesota had earned for him wide recognition as a chemist, especially in the field of dairy science and nutrition. He was the first recipient of the Borden Award for outstanding research in the chemistry of milk.

While Dr. Palmer's investigations carried him into many of the broad phases of nutrition and vitamin values, his principal interest was in such fields as the pigments of milk and butter, the cause of butter defects and storage troubles, the physical and colloid chemistry of milk and the churning process. He carried out extensive research in animal nutrition, with stress on the mineral needs of dairy cattle and the relation of feeding to dairy production and quality.

NEWS and VIEWS

Science and Research in Great Britain

THE debate which took place in the House of Commons on April 19 on Sir Granville Gibson's motion urging "the declaration of a bold and generous Government policy of financial assistance directed to the expansion of teaching and research facilities in our universities and technical colleges, to the extension of pure and applied research in all fields by the State, by industry through private firms and research associations and to the effective and rapid application of the results of research", in connexion with which the White Paper on Scientific Research and Development (Cmd. 6514) had been issued, covered much of the ground of recent reports of the Parliamentary and Scientific Committee and other bodies, as well as the recent lectures on science and industry arranged by the Manchester Chamber of Commerce. Sir Granville said that in regard to the research associations the Government grant has not increased in proportion with the increase in contributions from industry. An increase in expenditure on research of anything up to £15,000,000 would be a valuable investment for the country's future. Like Mr. Edmund Harvey and others who followed, Sir Granville pointed out that the staffs of the research and scientific departments of the colleges of Great Britain are far too small, and Mr. Salt, who followed him, urged that the number of research workers should be doubled. On particular fields of research, Mr. Salt instanced coal research as specially important ; Sir Ernest Shepperson stressed the need for agricultural research, particularly in relation to nutrition, and was supported by Mr. R. C. Morrison, Dr. Haden Guest and Major York, as well as by Mr. Snadden, who referred especially to veterinary research ; Sir John Graham Kerr referred to fisheries research, while Mr. Owen Evans and Mr. James Griffiths directed attention to the neglect of geological research and surveys. Sir George Schuster said that more attention should be given to our failure to make full use of the knowledge gained from the limited research carried out, and urged that, first, a more scientific frame of mind must be created in British industry ; secondly, closer contact should be established between those engaged in pure scientific research and those concerned with its practical applications ; and thirdly, means should be found to assist the development stage and the practical evolution of new industrial ideas.

The Lord President of the Council, Mr. Attlee, replying on the debate, said that the amendment was in full accord with the policy which the Government is following now and which it desires should be followed in the post-war period. The Government is fully alive to the fact that the winning of the peace will depend largely on a full and right use of scientific men and organizations. Assistance will be given in a bold policy, and the Government will take a lead, but it must be backed by a readiness to use the results of that research and by public opinion. The nation must become more aware of the importance of science. We shall be utilizing scientific methods throughout our activities of Government and of industry, and industry must be ready to take advantage of the new openings which the application of scientific research affords. The Government is also examining the need for the establishment of a fund to meet the cost of developing new inventions and of providing facilities for testing new ideas for industry, as well as how best to fit this in with the work of the co-operative research associations. The Government is also entirely in favour of generous support for the extension of teaching and research in the universities of Britain, but Mr. Attlee questioned the practicability of any statutory university advisory council. Mr. Attlee, welcoming references in the debate to the remuneration of scientific workers, said that the whole question of the relative remuneration of scientific workers in Government service is under investigation and steps have already been taken to raise the remuneration of the heads of research institutions. He thought a Ministry of Science would be a great mistake : what we need is to see that there are persons in all departments who are trained in the scientific method and appreciate what it means. Finally, he referred to the considerable improvement in the machinery of government through the creation of a Central Statistical Section and a Central Economic Section. He welcomed the debate as promoting the formation of an informed public opinion which would support a sustained effort.

Control of German Chemical Industry

IN the House of Lords on April 18, Lord Vansittart raised the question of the control of German chemical industry after the War. In particular, he asked for the appointment of a committee of scientific men to prepare a suitable scheme for the control or elimination of Germany's nitrate and hydrogenation plants. Such control might involve a close watch on German scientific education and research, and even the limitation of manufacture of certain high-precision instruments. There will be general agreement with his view that scientific men are best able to devise means to achieve such restriction and control. Lord Vansittart was supported by Lord Horder, who mentioned two synthetic drugs, used in the treating of sleeping sickness and malaria respectively, the supply of which had been deliberately restricted in countries outside Germany as a part of the Nazi preparation for total warfare. Lord Strabolgi and Lord Farringdon sounded a note of caution, pointing out that to cut down German nitrate production unduly would have a harmful effect on European agriculture and would in the end impede the work of re-establishing the health of the people.

The Government reply was given by Lord Cherwell, Paymaster-General. He said that various committees have been considering the questions involved, and the Government intends not only to call in more expert advice but also to give great attention to the recommendations made. He agreed that to prevent Germany from manufacturing nitrate and ammonia would create difficulty in supplying Central Europe with fertilizers, but German research will have to be supervised. The question of the control of German chemical industry is part of the much larger question of curbing the German war potential, and the Government is prepared to take every step possible to achieve this end.

It is indeed welcome news that the Government has this matter under consideration, and that scientific workers, whose special competence in this field is obvious, are to take a prominent part in formulating policy. It will be recalled that the matter was raised by Sir Robert Robinson so long ago as early in 1943, at the annual luncheon of the Parliamentary and Scientific Committee, and some of the problems involved have been discussed in these columns (see

NATURE, 151, 455 and 562; 1943). No time should be lost in bringing together those with the widest knowledge of the chemical, engineering and industrial problems involved, in order that a practicable scheme of control may be ready for operation as soon as hostilities cease.

Science and Industry at Manchester

IN presiding at the last of the series of meetings on "Science and Industry", arranged by the Manchester Chamber of Commerce, on April 20, the president, Mr. A. H. S. Hinchliffe, stated that to give continuity to the interest stimulated by the meetings and improve the liaison between scientific workers engaged on research and the industrial and commercial world, the Chamber has been discussing with the University of Manchester the formation of a joint standing council the members of which would be nominated by the University and the Chamber. The Cotton Industry Research Association is to be invited to take part in the work of the proposed council, which is intended to be an advisory and consultative body. While its precise functions cannot yet be defined, it is hoped that the results of research work would be constructively examined and discussed and the workers benefited by access to the experience of firms in the area. At the same time, business people would be assisted in their quest for new knowledge and in the solution of difficulties. It might even be possible to establish a bureau of information, and the range of subjects open for discussion in the council would cover economics and sociology as well as technical matters. The council's aim should be to stimulate an advance of thought and encourage enterprising action, primarily in the North-Western area but, it was hoped, also in a much wider sphere. Sir E. Raymond Streat urged, in supporting the proposal, that if, in the coming age of research, we could weave the life and work of the University of Manchester into the life and work of the great industrial area and commercial centre which surrounds the University, we might produce a great vitalizing force. The interest evoked by the meetings shows that people holding responsible positions in industry and commerce in Lancashire realize that only by a fertile marriage between science and industry can we establish and maintain the margin of superiority essential for post-war prosperity. He suggested three main objectives: to be first with new inventions and discoveries and promptest in their application; to be quickest and surest in diagnosis of economic and technical trends; and to be foremost in economizing costs so as to be more competitive without lowering wages. The age of research does not imply disaster for all small firms, though their managers will need much fuller scientific and technical attainments than was customary in the past.

Fundamental Scientific Research and the State

SIR EDWARD APPLETON'S final address in the Manchester series dealt with "Fundamental Scientific Research and its Practical Importance". Sir Edward said that he believes it is still necessary to insist that there is no barrier between so-called pure and applied research. There is great danger that the general public should regard the scientific man as one whose sole task is to produce a succession of discoveries of immediate use to industry, or of direct use to the individual member of the community. The main theme of his address was the wisdom of ensuring that there should continue to be in Great Britain many active research groups the scientific work of which would be that of free inquiry and the extension of man's knowledge of Nature, without concern as to whether the final results are of practical use to humanity or not. Emphasizing and illustrating the way in which most of the scientific developments of the present century had their origin in purely scientific work conducted with no thought of utility, Sir Edward pointed out that we also owe to workers in the field of pure science the scientific method of inquiry by observation, experiment and theory. It is, of course, also important that there should be practical men eager to test the properties of the new compounds and materials, and that applied scientists should keep themselves constantly in touch with the development of new knowledge, so that the gap between discovery and its application may be bridged as quickly as possible.

With regard to the conditions of success in fundamental research, chance often plays an important part. Fundamental research flourishes most abundantly in an atmosphere of freedom and, accordingly, Sir Edward believes we must look to our universities for the main body of our fundamental research. We must also recognize the importance of the man of exceptional originality and imagination, and see that he is supplied with the facilities he needs. Industrial research organizations and Government research departments should also contribute to the general body of fundamental knowledge, and he believes it to be the function of the Agricultural Research Council, the Department of Scientific and Industrial Research and the Medical Research Council to pursue fundamental research in fields which are ultimately likely to be of practical benefit to the community. Both Government and industry are awakening to the importance of scientific research and the need for its extension and application, but the large post-war developments in industrial research and technology must be sustained by an adequate volume of fundamental research.

United Nations Educational Reconstruction Plans

A TENTATIVE draft constitution for a United Nations Organization for Educational and Cultural Reconstruction was accepted by the Conference of Allied Ministers of Education at a meeting on April 19. If adopted by the Allied and Associated Governments, it will permit joint efforts in this field in line with parallel work already being developed by the Food Conference and the United Nations Relief and Rehabilitation Administration. The projected Organization would direct its activities at first to the emergency work of restoring the educational systems and the cultural institutions destroyed by the Axis Powers. Experience gained in carrying out these emergency tasks would create a basis for lasting international co-operation in educational and cultural fields. The proposed constitution was drafted at two open meetings convened by the Conference of Allied Ministers of Education and the American Education Delegation, led by Congressman Fulbright, which came to London early this month to work out plans for American collaboration with the Conference. The meetings were attended by representatives of all member and observer States currently interested in the Conference and were presided over by Mr. Fulbright. The device of holding open meetings enabled all representatives

present to participate fully, equally and without prejudice to their positions in the Conference.

The text of the tentative draft constitution for the proposed Organization consists of seven sections. It opens with a statement of the underlying reasons why international co-operation in educational reconstruction should be attempted. The functions of the projected Organization are then defined in terms which should permit it to work effectively in the fields of educational and cultural rehabilitation and reconstruction, and to develop ultimately into a permanent body with broader activities. Membership is to be open to all the United Nations and Associated Nations and to such other nations as shall be accepted by the assembly, upon application thereto, after the cessation of hostilities with the Axis Powers. Provision is made for an assembly with equal representation and votes for all member States, an executive board to be elected by the assembly and an international secretariat. The financial section states that administrative expenses shall be shared by the member nations on a basis to be agreed by the assembly. It also provides for the creation of an Emergency Rehabilitation Fund controlled by a committee, which will fix contributions and also make allocations from the Fund. The committee will consist of representatives of the three States making the largest contributions for administrative expenses and three members elected by the executive board. Member nations would be required to supply information about education and cultural matters. Provision is also made for defining the legal status of the Organization and its staff, providing for co-operation between the Organization and existing international organizations in the educational and cultural fields, and governing the relationship of the Organization to any agency for co-ordinating public international organizations.

Clinical Use of Penicillin

THE issue of the *British Medical Journal* dated April 15 includes eight papers which record the results of work done at one of the four main centres established in March 1943 by the Penicillin Clinical Trials Committee of the Medical Research Council. A leading article comments on these papers and on other work in the United States, where much larger supplies of penicillin are available, so that work on a larger scale is possible. In the first article, Prof. L. P. Garrod and Dr. Christie describe the work and policy of the centre at which all this work was done. Other articles deal with the systemic administration of penicillin by continuous intravenous drip, intramuscular injection, drip transfusion into the bone marrow of the sternum and continuous intramuscular drip transfusion; with the effects of penicillin on infections of the mandible and of bone, the latter indicating that treatment of chronic bone infections is not yet satisfactory; with its use as a local application to lesions of soft tissues (wounds, abscesses, cellulitis and infected skin eruptions); and its effects on breast abscess and certain skin diseases.

A final article by Prof. Garrod explains the extensive laboratory work which is necessary if the clinical work is to be properly controlled. Penicillin is supplied in the form of a powder or tablets and solutions have to be made from these. Because penicillin is a very labile substance, and because many bacteria are quite unaffected by it and may, therefore, live in these solutions or even decompose them so that they lose their activity, the greatest care is necessary in making up the solutions. Further, it is advisable to determine, before treatment, what micro-organism is being treated and the sensitivity of the particular strain concerned, because certain strains of some kinds of bacteria (especially Staphylococcus) vary in their resistance to penicillin. It is also necessary to obtain swabs from the patients to check by *in vitro* methods the effects of treatment. Because the therapeutic effect depends on keeping up a sufficient concentration of penicillin in the lesion, the concentration actually being maintained must be ascertained from samples taken from the patient. Estimations of the penicillin content of the blood are also done.

It will do no harm, perhaps, to repeat Prof. Garrod's reminder that it is of the first importance to realize that penicillin acts only on certain bacteria, most of which are Gram-positive, the chief exceptions being the gonococcus and meningococcus; and that certain bacteria are highly resistant to it. On the other hand, it has, he says, enormous antiseptic power, is almost completely indifferent to the medium in which it acts and almost completely non-toxic to the body as a whole. Clearly everything possible is being done in Great Britain and elsewhere to apply this remarkable antibacterial substance to the relief of suffering in man and animals. Those who impatiently demand quicker progress are evidently unaware of the great difficulties involved, and are often incapable of assessing the scientific care required, or the dangers of drawing premature conclusions from the extensive experimental work that is being done.

Warrington Yorke Memorial Fund

THE death of Prof. Warrington Yorke, tragically unexpected by those who knew his vigour and force of character, was a great loss to the Liverpool School of Tropical Medicine and to medicine and biology. His work on the trypanosomes, the nematodes and on other parasitic and tropical diseases earned for him an international reputation, and his later work on the chemotherapy of parasitic diseases was of equal value. It is said of him (*Brit. Med. J.*, April 15) that his introduction of drugs of the diamidine series is making it possible to master kala-azar in places where it is resistant to compounds of antimony, and tribute is paid to his efforts to place British chemotherapy in the front rank. Not only the former colleagues and friends of Warrington Yorke, but also all who respect and admire scientific ability and devoted effort to apply it to the relief of human and animal suffering, will like to know that their admiration may take a practical form. The Council of the Liverpool School of Tropical Medicine is appealing for funds to establish the Chemotherapeutic Research Department of that School as a fitting memorial to Warrington Yorke, who started the work now going on in it. Subscriptions may be sent to the Hon. Treasurer, Warrington Yorke Memorial Fund, Chamber of Commerce, 1 Old Hall Street, Liverpool.

Tattersall Memorial Fund

PAST and present students of the Department of Zoology, University College, Cardiff, have opened a Tattersall Memorial Fund, the object of which is to found a studentship in zoology in the College as a memorial to the late Prof. W. M. Tattersall, who died on October 5, 1943. The organizers of the Fund also desire to invite the many friends of Prof. Tattersall, particularly zoologists, in various parts of the world, to join them in perpetuating his memory.

Information may be had from Mr. G. E. H. Foxon, who is acting as the honorary secretary and treasurer of the Fund, at the Department of Zoology, University College, Newport Road, Cardiff, and to whom donations should be sent.

Earthquakes Registered at Fiji

THE first seismological bulletin has been received from the acting director of the Meteorological Office at Suva (Dr. W. Ralph Dyer). At this station a Milne-Shaw horizontal seismograph has been set up to register north-south movements, the co-ordinates of the station being latitude 18° 08′ 56″ south, longitude 178° 27′ 26″ east. The first earthquake to be recorded officially at this station occurred on July 31, 1943. Thirty earthquakes were registered in August, and up to September 21 twenty-two earthquakes were registered during September. On September 21 the seismograph was temporarily out of action owing to delays in the supply of photographic paper. The initiation of this new station is warmly welcomed. The attention of the Seismological Committee of the British Association for the Advancement of Science to this matter has been mentioned previously in the columns of NATURE, and the new station is also receiving assistance from the Dominion Observatory at Wellington, New Zealand. The Fiji Seismological Station is in an excellent position for the recording of the frequent earthquakes and tremors, a large number of which are submarine, in that Pacific region.

Town and Country Planning Association

THE Town and Country Planning Association will move to the Planning Centre, 28 King Street, Covent Garden, London, W.C.2 on May 8. The new premises provide a room for public meetings (including the Association's fortnightly lunch-time meetings), space for exhibitions and film shows and a meeting room for the Association's members and guests. The Association's library service will be greatly extended and an information service will be made available to deal with all aspects of town and country planning. The Association has arranged an exhibition "The English Town: its Continuity and Development", which is being taken to various parts of England during the next few months, and also an exhibition and film "When We Build Again".

Comet Schaumasse

PROF. H. SHAPLEY reports a telegram received from Strömgren and Lundmark announcing the rediscovery of this comet on March 30. The elements of its orbit and an ephemeris are given in the "Handbook of the British Astronomical Association", 1944. Perihelion passage took place about November 27.

Research into Problems of Hearing and Deafness

BY arrangement with the Medical Research Council, an Otological Research Unit has been established at the National Hospital for Nervous Diseases, Queen Square, London, W.C.1. It is to be maintained jointly by the Council and the Hospital, as in the case of the existing Neurological Research Unit. The director is Dr. C. S. Hallpike, a whole-time member of the Council's scientific staff and aural physician to the Hospital. The Medical Research Council, also, has appointed three new committees to advise and assist in promoting a general programme of research work into problems of deafness. They will deal with the following divisions of the subject. (*a*) Medical and surgical problems of the causation, prevention and treatment of deafness (chairman: Prof. H. Cohen, University of Liverpool). (*b*) Electro-acoustical problems relating to the design and application of instruments used in the investigation and alleviation of deafness (chairman: Dr. W. G. Radley, Post Office Research Station). (*c*) Problems relating to the educational treatment of deafness in children and adults (chairman: Prof. F. C. Bartlett, University of Cambridge). The membership of the committees includes nominees of Government departments and various bodies concerned with the practical questions which are involved.

Birds of Ceylon

MR. P. DERANIYAGALA, director of the National Museums of Ceylon, writes, pointing out that in the obituary notice of Hugh Whistler appearing in NATURE of August 21, 1943, no reference is made to his last major work, the avifaunal survey of Ceylon by the British and Colombo Museums. Whistler worked out the collections, and the results are now being printed in the Colombo Museum journal, *Spolia Zeylanica*; they should be published by about May.

The Night Sky in May

FULL moon occurs on May 8d. 07h. 28m. U.T., and new moon on May 22d. 06h. 12m. The following conjunctions with the moon take place: May 20d. 13h., Mercury 2° N.; May 24d. 04h., Saturn 2° N.; May 27d. 01h., Mars 1° N.; May 28d. 10h., Jupiter 1° S. There is only one occultation during May, and that is of 56 Gemi. on May 25d. 21h. 00·1m. (*D*). Mercury is in inferior conjunction on May 2 and is stationary on May 14. The planet rises about the time of sunrise in the middle of the month and forty minutes before sunrise on May 31. Venus, rising shortly before the sun throughout May, is not very well placed for observation. Mars moves from the constellation of Gemini into Cancer about the middle of May and is visible during the early part of the night. On May 1 the planet sets at 1h. and on May 31 at 23h. 48m. Jupiter is in the constellation of Leo and sets at 2h. 10m. and 0h. 19m. at the beginning and end of May. Saturn, in the constellation of Taurus, is drawing near the sun and sets at 23h. and 21h. 19m. at the beginning and end of the month. The η Aquarids are active during May 1–6 and can be seen in the early morning hours. The radiant is close to R.A. 22h. Dec. $-2°$.

Announcements

SIR JOHN MARSHALL, formerly director-general of archæology in India, has been awarded the Gold Medal of the Royal Asiatic Society.

PROF. W. N. HAWORTH, professor of chemistry in the University of Birmingham, has been elected president of the Chemical Society.

THE Committee on Nutrition Surveys, set up by the English Group of the Nutrition Society, a year ago, has drawn up a list of investigations, recent or in progress, into: (*a*) Consumption of Food; (*b*) Nutritional State; and (*c*) Effect of Supplements on Health and Efficiency. The number is unexpectedly large. A list of these investigations will be sent to anyone working on the subjects, on application to the director, Prof. J. R. Marrack, Advisory Committee on Nutrition Surveys, Bureau of Nutrition Surveys, London Hospital, E.1.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

The Osmotic Balance

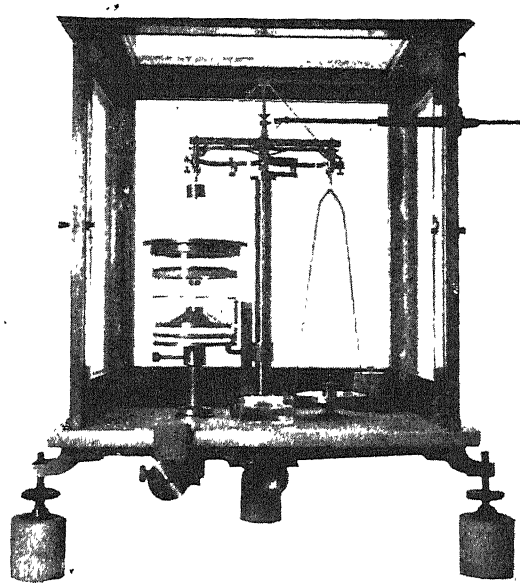
IN the case of polydisperse high polymers, different methods of molecular weight determination give different kinds of average values[1]. The two most important absolute methods are ultra-centrifuging and measurement of osmotic pressure. In the first case one gets, according to the method of calculation used, either weight averages or so-called z-averages, while osmotic pressure measurement always gives number-averages. The knowledge of several different average values for one substance helps us to judge the degree of polydispersity. When dealing with thread-like molecules of high molecular weight, the osmotic measurements are rendered difficult partly by the fact that even comparatively dilute solutions of this type possess high viscosity, partly owing to breakdown of the ideal gas laws at experimentally usable concentrations. One therefore has to resort to a suitable extrapolation procedure for obtaining correct zero-concentration pressure values. These circumstances make it necessary to perform the osmotic measurements at as low concentrations as are experimentally possible.

The methods so far used have aimed at determining the position of a liquid meniscus in a capillary, either by measuring the height of a column at equilibrium[2,3,4], or by applying a variable counter-pressure against the meniscus and measuring its rate of migration at different values of the counter-pressure[5,6].

In order to make it possible to determine lower osmotic pressures than the above-mentioned procedures allow, we have constructed an osmometer, in which the liquid passing through the membrane is weighed. It can be used for osmotic pressures from a few centimetres of water pressure and downwards to some hundredths of a centimetre.

In an undamped analytical balance one of the scales is removed, and on the floor of the balance case is fixed a stand with an adjustable platform carrying a glass cylinder filled with solvent. The osmotic cell is constructed of aluminium and glass, the necessary cementings being made with lead-oxide-glycerine. The lower part of the cell is conical with a basal diameter of 5 cm. At the apex is fixed a glass tube a few centimetres in length and of 0·9 cm. inner diameter. The upper part of the glass tube has an aluminium collar, carrying a wire so that the cell can be hung on the balance arm. A semi-permeable membrane is attached to the base of the conical recipient by means of a threaded ring and a perforated membrane-support. The membrane itself acts as packing material against leakage. The osmotic cell and part of the glass tube is filled with solution and suspended on the balance in such a way that it dips into the solvent contained in the glass cylinder. The whole apparatus is placed in a constant-temperature room.

By means of the adjustable platform the difference in level between the solution in the cell and the solvent in the glass cylinder can be varied. The balance is adjusted to neutral equilibrium. When the weight of the cell increases, the cell sinks until the buoyancy compensates the increased weight. Because of the minuteness of the displacements, the reading of the balance is magnified by means of a beam of light, doubly reflected from a mirror fixed to the balance.



THE OSMOTIC BALANCE.

In order to prevent evaporation, the glass cylinder is provided with a suitable lid perforated in the middle to admit the suspension wire. An open dish with solvent placed inside the balance case delivers solvent vapour to the air, thus diminishing evaporation losses. The creeping of the solvent along the inner wall of the cylinder is prevented by a collar fixed to this wall and filled with solvent. Electrostatic effects, which would disturb the weighing, are eliminated by means of a metal netting placed on the bottom of the cylinder and connected to the lid and to the cell through the suspending wire.

Experiments with the above apparatus have been carried out on nitrocellulose dissolved in butyl acetate. As semi-permeable membrane, 'Ultracellafilter' was used. It takes a considerable time for osmotic equilibrium to be reached and, therefore, a compensation procedure, involving the measurement of the velocity of migration of solvent through the membrane at different levels in the osmometer, was adopted. The osmotic pressure is found by interpolation.

As reference point for the measurement of the difference in levels between solution and solvent is taken the position when the meniscus in the cell is in line with the meniscus in the cylinder. Different adjustments of this position are reproducible to 0·01–0·02 mm. From this starting position all level differences are calculated by means of the corresponding weight differences.

It is necessary to introduce a correction for the rise of the solution owing to surface tension. This is done through null-experiments with solvent both inside and outside the cell.

The following example demonstrates the accuracy obtained so far. The nitrocellulose used as test material was made from American linters and had a nitrogen content of 12·28 per cent. The solvent used was normal butyl acetate, temperature 25° C. The correction for capillary rise was found to be 0·028 and 0·029 cm. in two null-experiments.

Concentration (gm. per 100 gm. solution)	Osmotic pressure (cm. butyl acetate)
0·0501	0·089
0·0500	0·084
0·0500	0·087

Mean, 0·087 cm. butyl acetate.

The corresponding value for the molecular weight (number-average) is 148,000.

The result obtained would indicate an increase in accuracy compared with earlier procedures of a power of ten.

The investigation is being continued and further details will be published elsewhere. Financial support has been received from the following industrial concerns: AB Bofors, Nitroglycerin AB and AB Expressdynamit.

Organic and Inorganic Pyrophosphates as Shock-inducing Agents

IT was shown by Green[1] and Bielschowsky and Green[2] that injection of the sodium salts of adenosine triphosphate, obtained from Dyckerhoff's "myotoxin", into a variety of animals resulted in a shock-like syndrome. It was suggested that the pyrophosphate group might be responsible for at least some of the described effects.

Further investigations on the striated muscle product show that its adenosine triphosphate is present in the form of the magnesium salt.

It seemed important to analyse the shock-producing action of adenosine triphosphate by a comparison of the action of related compounds varying in the three components: adenosine – polyphosphoric acid – magnesium.

As to the polyphosphoric acid, a detailed study has shown that the injection of $Na_4P_2O_7 . 10H_2O$ does produce effects similar, in some respects at least, to those produced by adenosine triphosphate. To study the influence of the adenosine and magnesium in the molecule, solutions of the sodium and magnesium salts of adenosine triphosphate and inosine triphosphate were tested for their lethal and shock-producing potencies in the rat and mouse, and for their depressor activities in the cat. Both salt solutions were prepared from the corresponding barium salts (barium inosine triphosphate from barium adenosine triphosphate by deamination with sodium nitrite), avoiding excess of magnesium, and their concentrations were checked by estimations of nitrogen and 7 min. phosphorus.

A condensed summary of the results of the assays is given in Table 1, and some abstracted data showing a few of the effects in the whole animal are given in Table 2.

In both the mouse and rat, the lethal doses of the inosine compounds were significantly higher than those of the corresponding adenosine compounds. Some of the shock-inducing effects of the adenosine triphosphate salts are therefore presumably associated with the presence of the amino group of adenosine.

The findings with the sodium salts show that their lethal doses were significantly higher in terms of their pyrophosphate contents than that of sodium pyrophosphate, with the exception of sodium adenosine triphosphate in the mouse. The interpretation of these results is complicated by the fact that the lethal dose of sodium pyrophosphate in the mouse was more than twice that in the rat. In both species the influence of the amino group in the sodium adenosine triphos-

$Na_4P_2O_7$	93	119	144	37	28	29	93	60	72	2

phate is evident. Nevertheless, the polyphosphoric acid seems to be an important factor since, for example, the lethal dose of muscle adenylic acid is much higher than that of adenosine triphosphate.

The replacement of sodium by magnesium in inosine triphosphate much more than compensates for the loss in activity produced by the substitution of the NH_2 group in the adenosine triphosphate by the OH group (inosine triphosphate). This is shown by comparison of the results obtained with magnesium inosine triphosphate and the sodium salts of adenosine triphosphate and inosine triphosphate (Table 1).

It may be assumed, therefore, that the P_2O_7 group becomes biologically more active, at any rate so far as its shock-producing effects are concerned, when it is combined with both magnesium and either adenylic or inosinic acids. As we have been unable so far to prepare an inorganic magnesium polyphosphate suitable for injection, we do not yet know whether this is due to the influence of the magnesium ion on the polyphosphoric acid group.

The magnesium salt of adenosine triphosphate had the greatest potency of all the substances tested, and using minimal lethal doses a shock-like condition followed the injection much more rapidly (Table 2). It is noteworthy that the quotient P_2O_7/P_2O_7—magnesium adenosine triphosphate is the same in both species for magnesium adenosine triphosphate, magnesium inosine triphosphate and the striated muscle product (Table 1), whereas there is a considerable difference between the rat and mouse in the quotients for both sodium adenosine triphosphate and sodium inosine triphosphate. A calculation on the basis that all the adenosine triphosphate in the striated muscle product is present as the magnesium salt accounts fully for its vaso-depressor activity (see Table 1). Its lower shock-producing potency after intraperitoneal injection is probably due to a slower rate of absorption of the magnesium adenosine triphosphate from the crude muscle product. All the data at our disposal make it highly probable that the adenosine triphosphate in striated muscle is present in the form of the magnesium salt. This conception is in good agreement with the results obtained by Szent-Györgyi and his collaborators[3].

Reaction between Proteins and Formaldehyde

IT has been found possible to deamide animal and plant caseins by treatment with a solution of 1 per cent caustic soda for 40 hr. at 45° C. The desamido casein, when hardened with formaldehyde under neutral conditions, combines with the same amount of formaldehyde as does the untreated casein. In the presence of salts, acids (for example, saturated calcium chloride solution and hydrochloric acid) and formaldehyde, the neutral hardened deamided material combines with no additional formaldehyde, whereas the untreated neutral hardened casein may increase its formaldehyde content by about 100 per cent.

Partial deamination is also possible without the removal of amide nitrogen. The partially deaminated product combines with a reduced quantity of formaldehyde under neutral conditions. In contrast to this, the same partially deaminated product combines with a normal quantity of additional formaldehyde when treated with formaldehyde, salt and acid.

Further confirmation of the conception of a reaction between formaldehyde and the amide groups of proteins is given by experiments with the protein zein. Only 0·4 per cent of formaldehyde combines with this protein when it is hardened in a neutral solution. In the presence of salt and acid, however, its combined formaldehyde increases to 4·1 per cent. These figures are in keeping with the low amino and high amide contents of zein.

It is concluded, therefore, that at or near the isoelectric point of the protein, formaldehyde combines with the amino groups mainly derived from lysine residues. Under more acid conditions it combines with the amide groups which are attached to residues of glutamic and related acids. A more detailed account of the investigation will appear elsewhere.

Methionine in the Treatment of Liver Damage

RECENT investigations on protein metabolism and nutrition have increasingly emphasized the importance of individual amino-acid deficiencies in producing specific clinical states and pathological appearances[1]. It has been shown[2] that fatty livers can be produced in rats by dietary control. This latter work, and the findings of Miller and Whipple[3] that methionine could protect the liver against damage by chloroform, suggested to us that the present epidemic of infective hepatitis and the increased incidence of 'post-arsphenamine' jaundice might in some measure be conditioned by a sub-optimal protein intake leading to a latent methionine deficiency.

In 1942 we commenced a series of investigations along three main lines: (*a*) the prevention of liver damage during arsenical treatment for syphilis; (*b*) the treatment of established liver damage in cases of infective hepatitis and 'post-arsphenamine' jaundice; and (*c*) the treatment of patients gravely ill with liver dysfunction extending over a period of many weeks or months. Our observations in the prevention of liver damage during arsenical treatment, to be published in detail shortly, have made it abundantly clear that liver damage can either be prevented or minimized by the administration of methionine or by the use of casein digests rich in methionine which have had cystine added to them. The addition of cystine apparently was of value because of the methionine-sparing action of the cystine.

Owing to the extremely variable severity of infective hepatitis and of 'post-arsphenamine' jaundice, the value of any treatment or treatments can only be appraised statistically and after many hundreds of cases have passed through our wards. So far, pre-

liminary results based on a study of 450 cases, including controls, would appear to show that the clinical course of the above diseases is influenced beneficially, and the period in hospital significantly shortened, by treatment either with pure methionine in properly regulated dosage or by feeding patients with rapidly absorbable casein digests rich in methionine. In gravely ill patients, the results obtained by methionine treatment have been so striking as to leave no doubt as to the efficiency of the treatment, especially in those cases which have remained jaundiced for weeks or months and were in a state of *icterus gravis* when methionine treatment was initiated.

All our work has convinced us of the importance of an adequate protein intake, and more specifically of those proteins rich in methionine, in preventing and treating liver damage due to widely differing causes. We can therefore substantiate in large measure many of the suggestions put forward by Himsworth and Glynn[4] as a result of their experimental work on rats.

Effect of Vitamin C on the Adrenaline Content of the Adrenal Glands of Guinea Pigs

I HAVE shown[1] that the insulin content of the pancreas is markedly diminished in scurvy. This may be due to a lowered vitality of all the tissues of the scorbutic animals or to the existence of a specific relation between vitamin C and the insulin content of the pancreas. As is known, the adrenal glands are concerned in carbohydrate metabolism. The adrenaline content of the adrenal glands was, therefore, studied in scorbutic and normal guinea pigs.

Guinea pigs on a scorbutic diet for 22–25 days, and guinea pigs fed with normal diet for 15 days, were starved overnight and the adrenal glands were removed next morning. The adrenal glands were extracted with trichloracetic acid for adrenaline and ascorbic acid according to the method of Rees[3]. This method was adopted as the value of adrenaline thus determined in adrenal gland extracts was found to correspond to that determined biologically. The results are summarized in Table 1 and the statistical analyses of the individual figures are given in Table 2.

TABLE 1.

	No. of animals	Average weight per animal	Weight of adrenal per 100 gm. body wt.	Ascorbic acid per gm. of adrenal	Adrenaline per gm. of adrenal	Adrenaline per pair of adrenals
Scorbutic guinea pigs ..	21	339 gm.	100·0 mgm.	0·035 mgm.	719·2 μgm.	223 μgm.
Normal guinea pigs ..	20	315	61·2	1·002	353·8	66

TABLE 2.

	Wt. of adrenal per 100 gm. of body wt.	Ascorbic acid per gm. of adrenal	Adrenaline per gm. of adrenal
Difference of the means	38·8 mgm.	0·967 mgm.	365·4 μgm.
Standard error of difference	6·187	0·13078	74·66
t	6·27	7·39	4·89
Remarks	Highly significant	Highly significant	Highly significant

The results show a highly significant increase in the adrenaline content of the adrenal glands in scurvy as opposed to the decrease in the insulin content of the pancreas[1]. The diminished insulin content of the pancreas of the scorbutic guinea pigs is, therefore, not merely due to the lowered vitality of the tissues of the animals. The action of vitamin C on the secretion of insulin appears to be specific in some degree, as the insulin content of the pancreas is not altered in vitamin B_1-deficiency[4], which also affects carbohydrate metabolism.

White Plumage of Sea-Birds

IN a recent communication[1] on this subject, Craik makes some suggestions which we have attempted to examine further. A simple experiment in which conditions natural to fish were imitated was made on the flat roof of the Zoology Building here. The observer looked vertically upwards through a glass trough filled with water at a piece of opaque cardboard 3 in. × 5 in. in size held 6 ft. above his head. The agitation of the water by the wind made visibility of details very poor. With any overcast sky, when the observer was presented successively with a black and a white piece of cardboard, he was unable to tell which was which. But when the sun was shining on them, the white cardboard was at once distinguished from the black.

Now it can be calculated that when the sky is overcast the brightness of a horizontal white surface illuminated by the light reflected from the sea is of the order of only a tenth of the brightness of the sky (the reflexion factor of water is 0·02 for normal incidence). Its contrast against the sky will thus be about 0·9, as compared to 1·0 for a perfectly black object. At close range the horizontal parts of a white bird or aircraft must therefore be expected to appear (like the white cardboard) very dark against the sky. The difference of contrast just mentioned can, however, affect the critical range of visibility. The light scattered by the air-layer between the eye and an aeroplane will decrease the contrast between the latter and the sky. The intensity of scattered light needed to reduce the contrast from the value at close range to the smallest contrast perceptible by man (of the order of 0·01) is 0·89 for a white object and 0·99 for a black object. If the intensity of the scattered light is proportional to the distance, one would thus expect the range at which they became invisible to be about 10 per cent shorter for white than for black aircraft. We have assumed here that the critical factor affecting visibility is intensity discrimination, that is, the retinal image is large and the value of the differential threshold is not dependent on its size. But as the range

of vision of fish is believed to be small, their threshold of visibility will scarcely be affected by atmospheric scattering and cannot depend only upon intensity discrimination as such. However, as Dr. Craik pointed out in discussion, when atmospheric scattering is negligible, the range of visibility of a white object will still be smaller than that of a black one. An object will become invisible when it is so far away that its image on the retina reaches a certain minimum size for any given brightness. If the threshold of visibility is a function of the product area by contrast only, then since area decreases as the reciprocal of the square of the distance, the difference in range should now be about half as great as it was for intensity discrimination alone. But the contrast to be taken into consideration here is the average contrast (say 0·8) of the object, rather than the contrast of the darker parts. The difference between the critical ranges of visibility of black and white objects will thus be again of the order of 10 per cent. It may be pointed out, however, that a black bird 10 per cent smaller in linear dimensions than a white bird would become invisible at the same range as the latter.

When the sky is clear, the situation is different. If direct sunlight strikes the white plumage of a bird, the latter will acquire a brightness of the order of 25,000 candles/m.^{2} (the sun giving an illumination of 100,000 lux)[2]. This brightness is much above that of blue sky, which is stated to be[3] 4,000 candles/m.^{2}. This agrees with what we observed in our experiment. In sunshine, white birds may therefore be very conspicuous to fish, and if anything more so than black.

It is therefore not clear that white birds are on the whole less easily seen than others, and in this way stand at an advantage. A closer analysis of the problem from the fish's point of view shows how complex it really is. For example, as the surface of the sea is generally agitated, it is not certain what a marine fish does see of objects in the air. Ward's[4] observations suggest that they would see very little. There are at the edges of the 'window' in the area of total reflexion dark ripples which may well be confused with birds. This casts doubt upon the implicit assumption on which the above calculations are based, namely, that the fish take action as soon as the bird becomes visible. Definite information is needed about the actual stimuli which make fish dive.

M. H. PIRENNE.

Psychological Laboratory,
Cambridge.

A. C. CROMBIE.

Zoological Laboratory,
Cambridge.
March 23.

[1] Craik, K. J. W., NATURE, 153, 288 (1944).

[2] Fabry, Ch., "Les Principes de la Photométrie en Astronomie et en Physique", Mémorial des Sciences Physiques, Fasc. XXIV (Paris, 1934).

[3] Walsh, J. W. T., "Photometry" (London, 1926).

[4] Ward, F., "Animal Life Under Water" (Cassell, London, 1919).

As Pirenne and Crombie have pointed out above, scattered light can, in the long ranges at which aircraft are spotted, have an effect on contrast which is not present at short ranges, but calculations for short ranges show that one might expect a considerable difference in spotting range for black and white birds. A considerable part of the brightness of a roughly hemispherical object such as a bird, seen from below with overcast sky, is contributed by skylight and not by light reflected from the sea. Estimating the reflexion factor of the bird's plumage at 0·9, this would make the mean brightness of the underside about 0·15 of that of the cloud background. This should have a definite effect on maximum spotting range, for at the human threshold, in clear air, the visibility of an object of high contrast is determined mainly by the total reduction in incident light or 'subtractive energy', that is, the contrast multiplied by the angular area. Thus an object of half the background brightness will require to have about twice the area, or to be brought to about $1/\sqrt{2}$ of the distance, to be visible. The same is likely to apply to fish (though their absolute visual acuity is poorer); and for objects blurred, as Pirenne and Crombie point out the image of the bird will be, by surface ripples. On this basis, a contrast of 0·85 should produce a 7 per cent reduction in spotting range, which is of the same order as that to be expected with aircraft. Further, the conditions of cloudless blue sky, under which the bird will be brighter than the sky, are rather rare in temperate climates and there will be other conditions, such as sun shining through breaks in cloud, in which the brightness of the bird may exactly equal that of the background.

Rough experiments with paper disks on white backgrounds confirm this, particularly for peripheral vision, in which human acuity is poorer and perhaps approximates more closely to that of fish. To exaggerate the contrast very slightly, and thus obtain definite results with relatively few readings, punched paper disks of dead black and grey paper 5 mm. in diameter were mounted on white card, giving measured contrasts of virtually 1·0 and of 0·75. They were viewed at 15° from the visual axis, at the following distances. A blank card was sometimes presented, and the number of times when the observer failed to report the presence of a spot was recorded; he took about 5 sec. to judge.

	Grey spot	Black spot	No spot
Observer A			
Errors at 4·2 m.	17/20	1/20	0/20
Errors at 3·75 m. (— 10%) ..	11/20	0/20	0/20
Errors at 3·4 m. (— 20%) ..	1/20	—	0/20
Observer B			
Errors at 3·8 m.	15/20	2/20	2/20
Errors at 3·4 m. (— 10%) ..	5/20	—	0/20
Errors at 3·0 m. (— 20%) ..	1/20	—	0/20

Thus the errors at the longer distance are markedly greater with the grey than with the black spot, and when the distance is reduced the errors on the grey disk decrease, equalling at somewhere between 10 and 20 per cent shorter range those obtained with the black disk at full range. This is in good agreement with the above theory, on which the reduction for this contrast should be $1-\sqrt{0\cdot75}$ or 13 per cent. Thus there should be some advantage in white plumage if fish dive as soon as the bird reaches threshold visibility, but I agree that whether in fact they do so should, if possible, be directly investigated.

K. J. W. CRAIK.

Psychological Laboratory,
Cambridge.

DR. K. J. W. CRAIK's suggestion[1] that the white coloration of sea-birds is adaptive in the sense of rendering them less conspicuous to their prospective victims cannot be considered convincing in view of the following difficulties.

A by no means negligible number of predomin-

antly white sea-birds, among them some albatrosses and shearwaters, do not feed mainly on living fish, but on organisms not endowed with sufficiently long sight for the coloration of the bird predator to be of importance. Some of these birds feed chiefly by night, when white coloration is not of any obvious advantage. Gulls are primarily scavengers.

It is difficult to believe that dark coloration would be a disadvantage to such a bird as a gannet plunging almost vertically at high speed on its prey. There is no evidence that gannets or boobies in immature brown plumage are thereby handicapped in catching fish. The same may be said of the dark-plumaged immature sooty terns.

Diving birds which hunt fish are not infrequently brilliantly coloured or dark—both those which dive from a perch or hovering position, such as kingfishers, or others, such as guillemots, mergansers and cormorants, which dive from the surface of the water.

The white coloration of some large birds, such as swans, appears to be related to their relative immunity from predators and not to feeding habits.

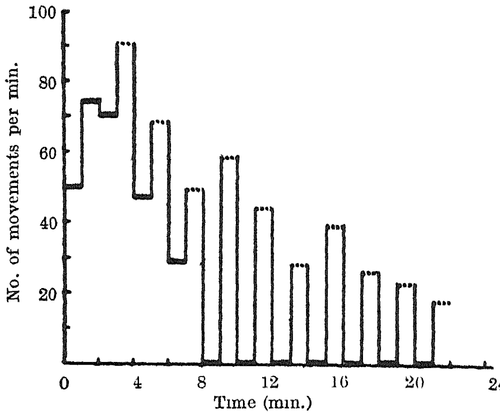
Immediate Effect of X-Rays on the Movements of Larvæ and Pupæ of Mosquitoes

DURING X-ray experiments with larvæ and pupæ of mosquitoes (Culex), irradiated specimens were observed to accelerate their movements immediately after the onset of irradiation. When the irradiation is interrupted, they return at once to normal behaviour. Since we could find no description of the phenomenon, we attempted to study it in detail, as it appeared to constitute an immediate reaction to X-rays.

Larvæ and pupæ of the mosquito *Aedes ægypti* were used, because they were available in numbers, and their movements can be readily counted. The number of movements per minute was taken as a measure of activity. In order to determine the activity of the larvæ and pupæ under normal conditions, their movements were counted during three consecutive minutes before the beginning of irradiation. This number varies in different individuals from 30 to 80 per minute. The individuals were then subjected to successive irradiations of one minute, alternating with interruptions of the same duration. One larva or pupa at a time was exposed to irradiation in hollow slides filled with water, the diameter of the hollow being 9 mm. Throughout each experiment the specimen remained in position under the X-ray tube, the interruptions of the treatment being effected by closing the X-ray exit with a lead shutter.

A demountable tube was used as X-ray source. The anticathode consists of copper and the exit of the rays is closed by a thin aluminium sheet 30 μ in thickness. The tube was operated with a tension of about 35 kV. max. and a current of 10 m. amp., the intensity being 38,000 r./min., the irradiated specimen being 38 mm. from the anticathode. The characteristic course of the experiments is shown in the accompanying graph. The activity during irradiations and interruptions was determined as described above.

The difference in activity during irradiations and



Activity of a pupa of *Aedes ægypti*

breaks is clearly seen. Activity is distinctly increased during irradiation by 20–60 movements per minute. As the experiment progresses the activity diminishes and finally ceases entirely during the breaks, whereas during the irradiation the specimen continues to move actively for a period of about half an hour and even more. Different individuals may react differently to the irradiation with regard to both rate of movement and time of cessation, but the general course of the experiment is uniform.

Cultures of Excised Leguminous Roots

WITH the development by White, Robbins, Bonner and others of a technique permitting the culture of root systems from excised root tips, the possibility arose that the method might profitably be employed in studies of leguminous root nodules. Certainly if it proved possible to secure nodule formation on root cultures, then the investigation of some problems associated with the symbiosis between legume and nodule organism would be facilitated. So far as I am aware, there has been only one published record of an attempt to secure the nodulation of excised leguminous roots, namely, that of Lewis and McCoy[1]. Working with excised bean roots growing in agar, they observed the development of four nodules upon one root out of sixty that were cultured.

I have investigated the possibility of inducing the formation of nodules on excised roots of maple pea (Pisum). Excellent growth of roots of this species has been obtained in the medium formulated by Bonner[2], which includes inorganic nutrients, sucrose, vitamin B_1 and nicotinic acid. The procedure adopted is to germinate surface-sterilized and imbibed seeds of maple pea on agar plates until the radicles are 1–2 cm. long. Tips 0·5 cm. in length are then excised and transferred to flasks containing a shallow layer of the sterile nutrient solution. From such tips, roots 10–12 cm. long have developed within two weeks, while after longer periods roots up to 40 cm. in length have been obtained, well supplied with laterals, without any renewal of the medium. The roots bear short root-hairs, but as noted by Bonner[3], no secondary thickening has been observed.

The inoculation, with appropriate nodule bacteria, of excised pea roots growing in the above culture solution has not resulted in nodule formation. The organisms multiply in the medium, forming slimy strands adhering to the root surface, but the brief microscopic observations so far made reveal no curvature or primary infection of the root hairs. This last point obviously deserves much fuller investigation.

It seemed possible that the nitrate of the Bonner medium might be exerting an inhibiting effect, since it is well known that the presence of combined nitrogen tends to reduce the extent of nodulation of a leguminous plant. Initial reduction of the level of nitrate, however, markedly reduces the growth of the excised roots themselves. The method was therefore adopted of transferring well-grown roots into a medium with reduced nitrate and then inoculating. Control roots remained healthy and showed some growth, but no nodules developed in the inoculated cultures. It was also observed that good nodulation can be secured on 'whole plant' cultures of pea growing with their roots immersed in the Bonner medium with full nitrate (no sucrose).

Attention has also been given to the possible effect of the sucrose content (4 per cent) of the Bonner medium. Tests carried out under aseptic conditions with whole pea plants growing in nutrient agar or in sand watered with the nutrient solution suggest that this concentration of sugar interferes with nodule formation (see table).

Concentration of sucrose (per cent)	4	3	2	1	0·5	0·1
Average number nodules per plant	1·2	3·2	4·0	6·2	12·5	16·3

The excised roots, however, require the 4 per cent concentration for vigorous development, a reduction even to the 3 per cent level leading to lessened growth. Well-grown roots were transferred to solutions low in sucrose before inoculation, but although the bacteria survived and multiplied, no nodules were formed.

It is obviously a possibility that the Bonner medium, though providing all requisite factors for primary growth, is short of some accessory factor necessary for nodule formation. In the intact plant this factor may pass down from the stem and leaves[4], although it may be noted here that in pea the current incidence of light upon the shoot does not appear to be necessary for nodule formation, since I have observed as many as 26 nodules per plant on fully etiolated plants rooted in agar[4,5]. Experiments in which top extracts have been added to inoculated excised roots have not resulted in nodulation. The findings of Wipf and Cooper[6] may be of significance in these attempts to secure nodulation on excised roots, which were no more successful with excised roots growing in agar media.

The above investigations (now interrupted) followed some preliminary work by Miss Helen Fraser, and were carried out during the tenure of a Robert Donaldson Research Scholarship under the direction of Dr. G. Bond, who also gave assistance in the preparation of this preliminary account.

Absorption in the Atmosphere and Decay of Cosmic Rays

IN a former communication[1], an account was given of the hourly records of cosmic-ray intensity which are being made in London by registering threefold coincidences between three trays of Geiger-Müller counters without using any absorbing screen. The full description of the apparatus is given elsewhere, together with a complete account of the analysis of the data corresponding to the first few months of observation.

For the first part of this analysis, the hourly numbers of cosmic particles averaged in groups of 24 hours were correlated with the barograph readings at the station averaged over the same intervals. The correlation coefficient thus obtained has the high value $-0·87$, and the barometric coefficient β represented by the slope of the corresponding regression line is $\beta = 3·45$ per cent per cm. mercury, or $2·53 \times 10^{-3}$ cm.^{2}/gm. This value of β is consistent with those formerly found by counter measurements, although greater in general than the value obtained with ionization chambers.

The principal object, however, of this provisional analysis of our data has been to separate the effects of absorption and decay which, on the hypothesis of the instability of the hard component, together determine the barometric coefficient. This separation has been made by establishing that the variation of the number N of cosmic particles at ground-level is a function first of the variation of the air mass (represented by the barograph reading B at the station) and secondly of the change in height $H - H_m$ of the pressure-level at which mesons are generated; this function is expressed by the equation

$$N - N_m = \mu(B - B_m) + \mu'(H - H_m),$$

where the subscript m refers to mean values. Clearly, μ represents the true absorption coefficient in air, and μ' the mean rate of decay of mesons.

We do not know the pressure at which mesons are formed; but it is possible to ascertain what would be the most likely pressure between 760 mm. and 75 mm., the heights of which can be found from meteorological observations. This can be ascertained by comparing the *partial* correlations $R_{NH,B}$, that is, the correlations for B constant, between the mean daily number of cosmic rays at ground-level and the heights corresponding to different pressure-levels for the same days. The accompanying table gives the values of $R_{NH,B}$ for the pressure-levels which have been chosen. Only the mean daily numbers of cosmic rays corresponding to days for which the meteorological data from the ground up to 16 km. were complete (80 in all) have been used, so that the values of $R_{NH,B}$ should be entirely comparable.

Pressure level	$R_{NH,B}$
75 mm. (16·1 km.)	$-0·67$
113 mm. (13·5 km.)	$-0·54$
188 mm. (10·3 km.)	$-0·32$
375 mm. (5·5 km.)	$-0·30$

The gradual increase of $R_{NH,B}$ with height, as shown by the table, seems to indicate that the appropriate pressure-level to be used in the equation is 16 km. or higher. On the other hand, the great significance of the value $-0·67$ for the corresponding correlation justifies the presence of the second term on the right-hand side of the equation, thus confirm-

ing the view that a part of the variation of the cosmic ray intensity at ground-level may be explained by spontaneous disintegration of mesons in the atmosphere.

The increase of the correlation with height does not imply, of course, that mesons are formed at the layer of 75 mm. pressure. They may be generated at higher layers, as suggested by the experiment of Schein, Jesse and Wollan[2]; but we can substitute for $H - H_m$ in the equation the fluctuations in height corresponding to 75 mm. pressure and thus obtain a first approximation to the regression coefficients. By so doing, and by applying the method of least squares, we obtain for the coefficient of true absorption :

$$\mu = 2 \cdot 28 \text{ per cent per cm. mercury, or } 1 \cdot 68 \times 10^{-3} \text{ cm.}^2/\text{gm.}$$

Ehmert[3] has measured the absorption curve in water and shown that the absorption coefficient down to a depth of 45 m. is given by the formula $\mu = 1 \cdot 56/h$, where h is the depth in gm./cm.^{2} On the other hand, from the theoretical results obtained by Rossi and Greisen[4] for the range of mesons in air, iron and lead, we have estimated that the ratio of the range in water to that in air would be about 0·9 for mesons of energy not greater than 10^9 eV. Assuming that Ehmert's formula is valid for air, and by applying the latter ratio to obtain the mass of water equivalent to the mass of air (thickness of the roof and counter-box included) above our apparatus, we obtain $\mu = 1 \cdot 65 \times 10^{-3}$ cm.^{2}/gm., which is nearly the same as that obtained from our observations.

For the second regression coefficient or mean rate of decay of the meson we obtain
$\mu' = 0 \cdot 054$ per km., or $0 \cdot 94 \times 10^{-3}$ cm.^{2}/gm.

Kolhörster and Matthes[5], by registering double coincidences while compensating for the variation of atmospheric pressure with a variable wood screen, have found for μ' the value $1 \cdot 15 \times 10^{-3}$ cm.^{2}/gm., which is of the same order. Taking into account, however, that no absorbers are used in our arrangement, allowance should be made for the amount of soft component which is recorded by the apparatus, and therefore the actual value of μ' should be greater.

For the mean range of the meson before disintegration, we have

$$L = \frac{1}{\mu'} = 18 \cdot 6 \text{ km.}$$

The mean life when at rest of a meson of 3×10^9 eV. energy would be $\tau_0 = 1 \cdot 6 \times 10^{-6}$ sec.

As to the temperature effect α, its value can also be obtained immediately by making use of Blackett's expression[6] $\alpha = - \delta z/L\delta\theta$. From meteorological data, $\delta z/\delta\theta = 0 \cdot 065$ km., for $z = 16$ km.; hence

$$\alpha = - 0 \cdot 35 \text{ per cent per } ^\circ\text{C.}$$

This value is greater than that generally found, but this was to be expected since α has been usually referred to the temperature near the ground.

Roozeboom's Type II of Solid Solution

ON p. 20 of Jänecke's "Kurzgefasstes Handbuch aller Legierungen" (Leipzig: Spamer, 1937), there is the following statement: "Es wurde früher vielfach noch ein Typus vollständiger Isomorphie angenommen, bei dem Schmelzpunkt-maximum auftreten sollte, obwohl hierfür niemals ein Beispiel gefunden war und auch schon von langen Jahren van Laar durch thermodynamische Betrachtungen nachgewiesen hatte, dass ein solcher Typus nicht auftreten könnte. Er wurde aber noch von Roozeboom angenommen, wodurch sich diese Auffassung noch in verschiedenen Lehrbüchern erhalten hat".

Early in 1939, I wrote to Prof. Jänecke (to whom I am personally unknown), asking him how he accounted for the existence of an apparent confirmation of this type in the well-known system *d*- and *l*-carvoxime (Adriani, *Z. physikal. Chem.*, 33, 469; 1900). The following is Prof. Jänecke's reply, dated April 24, 1939. "Das bekannte System: *d*- und *l*-Carvoxim und das neue: Malonsäure (—) monobornylester und M(+) ester ist kein Widerspruch mit dem von mir auf S.20 meines Buches gemachten Behauptungen. Es handelt sich in diesen Fällen ausgesprochenerweise um eine Verbindung, die beiderseits Mischkrystalle bildet. Es bilden sich entweder Mischkrystalle von $(d - l)$ mit d oder mit l. Die Darstellung zerlegt sich in zwei Teile. Vermutlich wurden sich bei organischen optisch aktiven Stoffen noch mehr Beispiele finden. Anderseits wird sich der Fall auf diese [word undecipherable] Verbindungen beschränken. In dem Nachtrag zu meinem Buche der Ende dieses Jahres erscheinen soll, werde ich hierauf noch kurz eingehen".

The reference to van Laar appears to be *Z. physikal. Chem.*, 63, 216–253 (1908), the crux of the matter occurring on pp. 235–236. Van Laar deduces the inequality :

$$(\alpha_2 - \alpha_2') < q_2 . \frac{T_1 - T_2}{T_2}$$

as the determining condition for a falling equilibrium temperature. T_1 and T_2 are the absolute melting points of the pure components, T_1 being the higher: q_2 is the heat of fusion of the lower melting component: α_2 and α_2' are constants determining the differential heats of mixing of the low melting component in the liquid and solid phases respectively. From here on I use van Laar's own words: "Ist nun $T_1 > T_2$ so ist das zweite Glied dieser Ungleichung immer positiv. Das erste Glied wird jedoch stets negativ sein, da die Grösse α_2' (welche die Mischungswarme in der festen Phase bedingt) in allen normalen Fällen $> \alpha_2$ in der flüssigen Phase ist. Die obige Ungleichung wird somit sicherlich stets erfüllt sein, so dass die Schmelzcurve wohl niemals bei der höchsten Schmelztemperatur zu steigen anfängt, und ein Maximum folglich so gut wie ausgeschlossen ist." I add that van Laar's demonstration is not, like many of the demonstrations of the Dutch school, dependent on van der Waals' theories of state.

The matter is of some importance, since many text-books of physical chemistry, including one with which I am myself associated, includes the erroneous diagram.

RESEARCH ITEMS

Antibiotics from *Aspergillus fumigatus*: Identity of Helvolic Acid and Fumigacin

The mould *Aspergillus fumigatus* gives rise to no fewer than four crystalline metabolic products possessing antibacterial activity. Of these, two compounds, fumigatin and spinulosin, have been definitely characterized and identified (Anslow and Raistrick, *Biochem. J.*, 32, 687 and 2288; 1938; Oxford and Raistrick, *Chem. and Ind.*, 61, 128; 1942). They are, in fact, closely related and have the constitutions 3-hydroxy-4-methoxy-2 : 5-toluquinone and 3 : 6-di-hydroxy-4-methoxy-2 : 5-toluquinone, respectively. A third product, helvolic acid, m.p. 204·5–212°, was isolated from *A. fumigatus* mut. *helvola* and described by Chain, Florey, Jennings and Williams (*Brit. J. Exp. Path.*, 24, 108; 1943). It is nitrogen free and has the empirical formula $C_{32}H_{44}O_8$ (deduced from ultimate analysis and X-ray mol. wt. data) and forms a monomethyl ester. Nothing further is known as to its constitution, but the substance is stated to be relatively non-toxic to animals, although active against Gram-positive organisms, for example, *Staphylococcus aureus* at 1 : 80,000, complete inhibition. Prior to this discovery another antibiotic from *A. fumigatus* was described by Waksman, Horning and Spencer (*Science*, 96, 202; 1942; *J. Bact.*, 45, 233; 1943) and was given the name fumigacin. It was stated to have a melting point of 185–187°, to contain 3·7 per cent of nitrogen and to be active against Gram-positive bacteria. In a forthcoming issue of *Science*, Waksman states that Menzel, Wintersteiner and Hoogerheide have demonstrated that fumigacin as prepared by Waksman contains some 20 per cent of gliotoxin, $C_{13}H_{14}N_2O_4S_2$, an antibiotic from *Gliocladium fimbriatum* and toxic to animals (Johnson, Bruce and Dutcher, *J. Amer. Chem. Soc.*, 65, 2005; 1943). On removal of the gliotoxin fraction, the purified fumigacin was found to be identical with helvolic acid in chemical composition, antibacterial activity and *in vivo* activity. The antibacterial metabolic products of *A. fumigatus* so far identified are therefore fumigatin, spinulosin, helvolic acid (or purified fumigacin) and gliotoxin.

Termites and Soil Fertility

A. M. Adamson, of the Imperial College of Tropical Agriculture, Trinidad, has discussed the relation of termites to soil fertility (*Trop. Agric.*, 20, 107; 1943). The most important of the activities of termites, in so far as they bear upon soil fertility, are probably: (1) consumption of dead wood and other plant remains, thereby accelerating the formation of humus; (2) movement of soil above the surface, for building nests and covered passages, thereby exposing the soil to weathering and promoting its admixture with humus; (3) making subterranean tunnels, which are exceedingly abundant and promote aeration, drainage and root penetration. In dry areas of sparse vegetation, the amount of organic matter in the soil may be seriously reduced if too many termites are present, but it is a subject which does not seem to have been investigated. Harvester termites attacking grasses denude parts of the velds of Africa, causing erosion. Much research, however, is necessary to elucidate the relations between soil fertility and the incidence of termites. Much work is also required on the composition of the materials forming the termitaria or habitations of these insects, and on their feeding habits in relation to organic matter in the soil. It is noteworthy that as regards their mode of life the termites fall into two natural groups. First, those of the family Kalotermitidæ, which live almost exclusively within dead wood. Their only activities affecting soil fertility are the consumption and disintegration of such material. The second group comprises the remaining families of the termites. Their members spend almost all their lives in intimate contact with the soil, and all of them apparently influence it in one way or another.

Laboratory Strains

R. Lamy (*Proc. Roy. Soc. Edin.*, 62, 9; 1943) has discovered an interesting divergence in the genotypes of different strains of *Drosophila pseudo-obscura*. This sheds some light on the validity of laboratory experiments for the solution of problems in the wild. She shows that backcrosses between Race *A* with marked *X*-chromosomes, and Race *B* of this species, sometimes exhibit non-viability of one or both sexes. Different strains differ in this reaction with a wild strain. The non-viability is greatly influenced by other genes on the autosomes. This divergence appears to be correlated with the length of time the strains have remained in isolation. The author suggests that the presence of a major gene in a strain may alter the selective value of many subsidiary genes, and this in turn would lead to a directional drift of the genotype as a whole. As a consequence, different strains containing one or more primary gene differences from another would be expected to diverge more and more from the original type.

Genetics of *Papaver alpinum*

A valuable analysis of the taxonomy, genetics and distribution of the group *Papaver alpinum* has been made by A. C. Fabergé (*J. Genetics*, 45, 139; 1943). This aggregate species has a more restricted range than *P. nudicale* but exhibits a considerable number of variants in the wild. These correspond to characters which are unifactorial in inheritance in cultivated *P. alpinum*. A diagnostic key and a distribution map are given by the author, who discusses the possible evolution of the group. The Sewell-Wright effect of random genefixation would appear to play a large part in the creation of a population uniform for apparently non-selectable characters. These populations may be relics. Eleven genes are identified. One locus has three allelomorphs. Linkage tests show the existence of two linkage groups, of which one has five loci and the other three loci. In the first group, covering seventy units, there is little interference, which is similar to the reported data in *Primula sinensis* and Zea and rather different from Drosophila.

Mosaic Disease and Fruiting of the Tomato

Reduction in the yield of tomato plants infected with mosaic virus has been described by several authors. A more detailed investigation has recently been made by Ireson W. Selman (*J. Pomol. and Hort. Sci.*, 20, Nos. 3 and 4, Oct. 1943). Mosaic-infected and healthy plants were studied at two levels of liming and three levels of potash manuring. The total number of flower buds per plant was not affected by mosaic infection, but was reduced by liming and the addition of potash. Total numbers of fruits were,

however, reduced by mosaic infection and by liming, but were unaffected by the level of potash. An interesting fact is that liming, potash manuring and mosaic infection all depressed the yield of fruit, suggesting that the tomato crop is not benefited by excessive manuring. This conclusion has recently been reinforced from other directions. Mosaic infection reduced the yield of fruit at all levels of lime and potash, and also increased the severity of severe blotchy ripening. This indicates a possible connexion between the virus and potash metabolism within the host plant. It focuses attention upon the need for careful control of potash manuring, particularly with the variety 'Potentate', on which the experiments were performed.

Mineral Resources of Eire

EMERGENCY PERIOD PAMPHLET No. 1 of the Geological Survey of Ireland (Stationery Office, Dublin) is a short review by D. W. Bishopp of Irish mineral resources and the possibilities of developing them. It is suggested that a limited quantity of coal will be obtainable for some time to come, though only with difficulty and expense, and that any rapid expansion of output to compensate for more than a fraction of the normal imports (now cut off) would be impracticable. In the case of metalliferous minerals, the mineral belt of Avoca still holds out some hope of further profitable exploitation. On the whole, however, the prospects of reviving an industry in copper are unfavourable, and the lead-zinc-silver deposits are also far from encouraging, though it is not overlooked that entirely new deposits or extensions of known ones may exist beneath the blankets of bog and glacial drift which hide vast areas of the underlying bedrocks. Of the non-metallic minerals which are at present being worked (structural materials ; rock phosphate in the Carboniferous beds of West Clare; gypsum in the Trias of Carrickmacross and Kingscourt; barytes in Co. Sligo; pyrites, for sulphur, in Avoca; and quartz from Muckish) there is no likelihood of a shortage in the near future.

Potassium *para*-Phenolsulphonate as a Buffer

THE pH range of 8·6–9·0, between those for borates and secondary phosphates, is usefully filled by potassium *para*-phenolsulphonate. The purified product is not commercially available, but E. E. Sager, M. R. Schooley and S. F. Acree (*J. Res. U.S. Nat. Bureau of Stand.*, **31**, 197; 1943) find that the manufactured material may be decolorized by treating a hot solution with activated carbon and recrystallizing three times. A quantitative method of analysis by bromine titration is described. Ultraviolet absorption spectra showed differences between the primary and secondary salt, and indicated that the sulphonate group is almost completely ionized in dilute solution. Now that detailed information is available, it seems likely that potassium *para*-phenolsulphonate should find useful application as a buffer substance. In the same journal (**31**, 205; 1943), R. G. Bates, G. L. Siegel and S. F. Acree describe measurements of the thermodynamic second dissociation constant K_2 of *para*-phenol sulphonic acid by means of electromotive forces of hydrogen–silver chloride cells without liquid junction, using buffer mixtures of the potassium salt, sodium hydroxide and sodium chloride. The results between 0° and 60° C. are given by $pK_2 = 1961{\cdot}2/T - 1{\cdot}1436 + 0{\cdot}012139T$ (T = abs. temp.). The pH values of buffers having the molal ratios m_1/m_2 of phenolsulphonate and bivalent phenolate sulphonate ion between 2/3 and 1 are given by $pH = pK_2 - \log (m_1/m_2) - 3A\sqrt{\mu}/(1 + 8B\sqrt{\mu})$, where μ is the ionic strength and A and B are constants.

Non-linear Optics and Electrodynamics

FOR the past two years the Dublin Institute for Advanced Studies has been engaged on a series of investigations of the consequences of replacing Maxwell's electromagnetic equations by those of Born and Infeld, which are non-linear. The first paper, entitled "Non-linear Optics", by Prof. E. Schrödinger (*Proc. Roy. Irish Acad.*, **47**, 77; 1942), dealt, among other matters, with the mutual influence of light waves. It showed that light is refracted by light, and that two light rays experience mutual scattering. Further developments were given in later papers (*ibid.*, **48A**, 91; 1942; and **49A**, 4; 1943). The extension to non-linear quantum electrodynamics was undertaken by J. McConnell (*ibid.*, **49A**, 149; 1943), and showed the great complexity of the problem. The results agree closely with those already obtained in Schrödinger's papers, but there are grave difficulties to overcome, which, it is suggested, may be resolved by using the theory of radiation damping due to W. Heitler and H. W. Peng (*Proc. Camb. Phil. Soc.*, **37**, 291; 1941; and **38**, 296; 1942). The final conclusion is that we arrive at a reasonable theoretical picture of a process, which has never actually been observed, but is certainly small enough not to be in contradiction with the present negative experimental evidence.

Solar Flares and Magnetic Storms

H. W. NEWTON, in a paper with this title (*Mon. Not. Roy. Astro. Soc.*, **103**, 5; 1943), deals chiefly with magnetic storms that follow intense flares after several hours. A large amount of observational data has been collected between 1859 and 1942, and details of the time, duration and position on the disk of thirty-seven intense flares are listed. In twenty-seven cases magnetic storms began within two days of the flares, and the percentage association is higher for the central zone of the disk (0°–45°). The occurrence of the smaller storms, which show a recurrence tendency, is explicable on the theory of a corpuscular stream emitted more or less continuously for weeks, partaking of the sun's rotation, and overtaking the earth in its orbit at intervals of 27 days. This view cannot be reconciled with the occurrence of the great magnetic storms, which show no pronounced tendency to recur at intervals of 27 days, and the following features are suggested as operating in the latter case. A newly formed corpuscular stream is ejected at the time and place of the great flare, and when this stream reaches the earth's orbit in a period of about 20–26 hours, the five greatest storms giving the former period, the earth itself is included in a 'head-on' encounter. The stream of corpuscles has a wide front, the semi-angle of the equivalent cone being often as large as 40°, and sometimes greater. Although it is concluded that for every *great* magnetic storm there is a high probability that it has been preceded about twenty-four hours earlier by an intense solar flare, the smaller storms still present a problem. They continue throughout solar minimum, when great sunspots, flares and great magnetic storms have temporarily ceased (see also NATURE, April 15, p. 452).

X-RAY ANALYSIS IN INDUSTRY

CONFERENCE OF THE X-RAY ANALYSIS GROUP OF THE INSTITUTE OF PHYSICS

THE third Institute of Physics Conference on X-ray analysis in industry was held in Oxford on March 31 and April 1. This year it was organized by the newly formed X-ray Analysis Group of the Institute and followed the first annual general meeting. Attendance was not, however, confined to members of the Group; indeed, non-members were in the majority among the two hundred present.

The chairman of the Group, Sir Lawrence Bragg, presided. In opening the conference he pointed out that the title "X-Rays in Industry" does not mean that academic work is excluded; one of the main objects of the Group is to link more closely the work of the universities and of industry. This point was well illustrated by the papers read at the first session. The subject—the analysis of complex organic compounds—may have appeared highly academic, yet in the discussion it was obvious that it is of great interest to, for example, the rubber and plastics industries.

Complex Organic Compounds

In the first paper, Dr. E. G. Cox pointed out that there is no royal road to success in solving crystal structures; there is still a great deal of trial and error work, and the computations involved may be quite extensive. He emphasized that, for a complicated structure, a large number of approximate intensities is better than a few accurate ones. Moreover, it is almost a necessity to use three-dimensional methods except when a flat molecule is being studied. This is due to the low resolving power, which is only about 0·5 A.; the projections of atoms on a plane often fall closer than this, but in three dimensions they cannot be closer than 1A. Accuracy should not be sought for its own sake, but where accuracy is required, crystallographers should state precisely what they have achieved. It is necessary, above all, that their results should be dependable.

Dr. Dorothy Crowfoot gave an account of the work upon which she had been engaged with Dr. C. H. Carlisle, on the structure of cholesteryl iodide. She led up to this by a brief summary of the work of Bernal on the sterols, and pointed out the difficulties that often attend the investigation of such crystal structures. These difficulties can sometimes be overcome if the structure contains a heavy atom, since this will largely determine the relative phases of the structure amplitudes. Cholesteryl iodide gave an opportunity of trying out these ideas in the general case, for it has no centre of symmetry. In spite of this, it was found possible to derive the complete structure of one of the forms.

Two-dimensional Fourier synthesis was used and was supplemented by the information given by line synthesis through the peaks in the projection. There was, however, an inherent difficulty in that the method gave the correct structure overlaid with its mirror-image, and in order to sort out the true structure, knowledge of interatomic distances had to be used. Apart from the operation of finding which peaks represented related atoms, the determination of the structure was entirely direct.

Mr. H. M. Powell described some recent work he had done in collaboration with Dr. Huse and Mr. Cooke. This had as its aim the discovery of the nature of the intermolecular forces in aromatic compounds. A large range of compounds was first reviewed to see which were likely to be solvable. In agreement with Dr. Crowfoot, he stressed the value of a heavy atom in the structure; but he showed that this can have its limitations also. For a molecule containing three iodine atoms the detail of the carbon atoms was completely 'swamped'; with only one iodine atom, however (*para*-iodoaniline-*sym*-trinitrobenzene), it had been found possible to work out the complete structure by successive refinement of two-dimensional Fourier synthesis. The result arrived at was that the forces binding the molecules are certainly not covalent, but are probably of the van der Waals type, although some of the interatomic distances are rather short. Mr. Powell concluded by showing X-ray photographs containing 'smear' lines, and gave a possible explanation based on 'mistakes' in the packing of the molecules.

In the discussion, Dr. C. A. Beevers expressed the opinion that three-dimensional Patterson synthesis should be applied to structures that will not succumb to the methods so far described. The method is to calculate sections at special values of the parameters. Dr. Smare agreed with the possibilities envisaged, but said that in carotene, $C_{40}H_{56}$, it is surprising how many chance peaks occur in such planes. Dr. Cox explained this by the lack of resolution.

Dr. K. Lonsdale pointed out the need for correcting for extinction before improving methods of measurement of intensities. She showed some 'divergent-beam' photographs of certain organic crystals. These were very poor, but after the crystals had been dipped in liquid air, greatly improved photographs were obtained. The poor quality of the original photographs was due to the presence of extinction; dipping into liquid air decreased the perfection of the crystals and so decreased the extinction. Dr. H. Lipson also questioned the accuracy claimed by some workers; he gave theoretical reasons for thinking that an accuracy of 0·02 A. could not be reached with Fourier synthesis. Dr. G. A. Jeffrey, on the other hand, instanced the remarkable consistency of bond-lengths derived from different crystals.

Mr. C. W. Bunn thought that trial and error methods still have a place in the determination of structures, and that they have been given a new lease of life by the optical method devised by Sir Lawrence Bragg. Essentially this method reproduces with ordinary light the diffraction of X-rays by a crystal, and a complete zone of intensities can be determined in about an hour even for a complicated structure.

Dr. I. MacArthur urged the use of the variation of physical conditions, particularly temperature. He showed a set of X-ray photographs that have in this way produced valuable evidence of the structure of the ketones.

Finally, Prof. N. V. Sidgwick questioned the generality of Mr. Powell's conclusion that the forces between aromatic molecules are of the van der Waals type; it might be true for one compound, but not for others.

Fibres

The first session on the second day was devoted to fibres and other types of imperfect structure. Dr. W. T. Astbury showed diffraction photographs of a number of fibres, including 'powder-like' fibres

giving very diffuse rings, stretched poly-*iso*butylene, which gives sharp spots, and keratin fibres which give intermolecular patterns. He also showed photographs of such protein fibres as porcupine quill, which give many orders of diffraction, showing evidence of a spacing of more than 600 A. in the structure. The former fibres give much sharper photographs when stretched, while the latter do not.

The physical properties of a fibre are changed considerably when the fibre is wetted, but its diffraction spectra remain the same. Different fibres with very different strengths can give photographs indistinguishable from each other. Thus X-rays do not yet give complete information about the technical properties of fibres, since the X-ray spectra are due to the crystallinity of the fibre, while the mechanical properties depend mainly on the less organized (amorphous) parts, which only affect the background of the photograph.

Dr. E. Aruja described some work on the structure of chrysotile, one of the asbestos minerals. He showed an X-ray photograph in which some of the spots are drawn out into streaks along the layer lines, owing to imperfection in the structure. Chrysotile is formed of hexagonal sheets of SiO_4 units alternating with brucite layers, and since these layers have slightly different cell dimensions the sheets may be expected to be curved. This accounts both for 'mistakes' in the structure and for the fibrousness of chrysotile. The photometer curves of the streaks have been correlated with Warren's calculations on the intensity of diffraction from imperfect layer structures. Antigorite, a substance having the same chemical composition as chrysotile, differs in having a lamellar structure.

Mr. C. W. Bunn spoke on the structure of high polymers. Although one cannot obtain single crystals of these, they can be partially oriented by stretching or rolling, and the amount of X-ray evidence available is generally adequate for structure determination. There is generally 5–10 per cent of disordered material in polymer specimens. The usual methods of structure determination are employed, except that little use can be made of Fourier methods. The intensities calculated from trial structures based on stereochemical knowledge are compared with observed intensities, the values of which can be estimated visually with sufficient accuracy. For this purpose all available spectra must be employed. When the most probable structure has been found, there may still be some disagreement between calculated and observed intensities; this may often be attributed to anisotropic thermal vibrations, rotation of chains about their axis, and the distortion of electron clouds in $=CH_2$ groups. This last effect has been observed in polyethylene, and confirmed by evidence from 'thermal' spots.

Prof. H. L. Riley gave a summary of the theory of the formation of coals, and described work done with the object of elucidating coal structure. Chars produced at various temperatures from a number of organic compounds show a remarkable constancy of particle thickness of about 10 A., as indicated by the breadth of the 0002 reflexion. This is not so with coals, which give particle sizes varying with the charring temperature, the variation being of a different form for different coals. Part of this variation may be attributed to the packing of flat units under the influence of thermal agitation, but this packing would appear to reach a limit at 550° C. For the cause of subsequent changes we must look to the effect of heat on other components of coal. It is therefore interesting to observe that particle sizes of dibenzanthrone chars show much the same variation with charring temperature as those of coking coals.

In the discussion which followed, Dr. D. P. Riley spoke of the study by X-rays of 'amorphous' materials, like carbon black, and said that diffraction photographs show three parts, interatomic, intermolecular and interparticle, the last-named occurring at the lowest scattering angles, and giving useful information about the particle sizes. Dr. G. Coumoulos described some plastics which always appear 'amorphous', in spite of stretching, owing to the presence of long side-chains in their structures. Dr. A. R. Stokes suggested that information about the form of 'mistakes' in a structure can be gained by using the fact that the only fuzzy reflexions are those for which the structure amplitude is changed by the mistake; the other reflexions are sharp.

Preferred Orientation in Wires and Sheets

The subject discussed in the final session was preferred orientation in wires and sheets. Dr. W. H. Taylor opened with a short account of the stereographic projection, which forms the basis of the pole-figure method of representing preferred orientation. He pointed out that, while the projection of a single crystal represents many planes, the pole figure of a polycrystalline material represents only one set; thus a series of pole-figures will in general be required for the same specimen.

Preferred orientation sets in after a material has been broken up into a mosaic structure by cold-work, that is, after the point at which fracture would have taken place in a straight tensile test. The mechanism of re-orientation involves both slip and twinning; but the latter has, as yet, received much less attention than the former.

Dr. Taylor then described some work on magnesium sheet containing 2 per cent of manganese. Transmission X-ray photographs were first taken; but the disadvantage was that only the average orientation over the whole thickness was studied. A better method was to take surface reflexion photographs and to examine the orientation at different levels by successive etchings of the surface. It was found that the basal plane (0002) of the hexagonal structure was brought approximately into the plane of the sheet. Below the surface a double orientation sets in, the basal plane tending to set at $\pm 15°$ to the plane of the sheet along the rolling direction. A complete description of the orientation is still lacking.

Mr. H. P. Rooksby described some results of the examination of tungsten and molybdenum wires and sheets. The drawn wire shows a texture characteristic of the body-centred cubic metals, [110]* tending to lie along the wire axis; this orientation is more closely approached the greater the reduction in diameter. Etching away the surface shows that the orientation becomes more nearly complete in the centre.

The rolling process restricts the orientation still further, since there is a tendency both for (100) to become parallel to the surface of the sheet, and for [110] to become parallel to the rolling direction. X-ray photographs show, however, that there is a

* Indices enclosed in round brackets represent planes; those enclosed in square brackets represent zone axes or directions in the crystal.

considerable deviation about the rolling direction. Successive rolling in two perpendicular directions reduces this deviation so much that the resulting sheet has almost the properties of a single crystal; in particular, it has a pronounced cleavage at 45° to the rolling directions, and this is very objectionable in practice. For this reason the successive rollings at right angles must be replaced by a uni-directional rolling.

Dr. J. T. Randall dealt with orientation properties of sheet steel for electrical machinery and transformers. Up to 4½ per cent of silicon is added to the iron from which these sheets are made in order to reduce the oxygen content and to increase the resistivity. The impurities left, however, still have a great influence on the magnetic and orientation properties of the material, which differ greatly from those of pure iron. The crystals in hot-rolled silicon-iron sheet are oriented with [110] parallel to the direction of rolling and (100) in the plane of the sheet, whereas cold-rolled (Goss) sheet has [100] and (110) in these orientations. The Goss sheet is therefore preferable for transformers, since [100] is the direction of easy magnetization and should therefore lie in the direction of the flux.

Dr. Randall emphasized the danger of introducing cold-work into the specimen; for most methods of X-ray examination it is usual to cut small pieces from the sheet, and the proportion of cold-worked to undeformed material is high. This difficulty cannot be overcome by etching, which itself may have some preferential effect. Methods which do not have these defects are the study of etch pits and the torque magnetometer.

In the discussion, Mr. G. C. Richer suggested that there may be disordered regions between the magnetic domains in transformer sheet; these cannot easily be detected by X-ray methods but they may influence the magnetic properties.

Dr. T. Ll. Richards underlined the necessity for using the stereographic projection, and described how he has studied the orientation of chromium plating.

Dr. W. F. Berg showed slides of some back-reflexion Laue spots from transformer sheet, and suggested that the fine structure they possess might give some information about slip planes in the crystals.

Mr. E. E. Spillett emphasized the importance of preferred orientation in aluminium. Nevertheless, there are still some problems left unsolved; for example, there does not appear to be any simple correlation between the hardness and the degree of preferred orientation in an annealed sample which was examined by X-rays. The orientation in aluminium tube is dependent on whether a reduction of diameter or of wall thickness predominates. In the former case, [111] is parallel to the tube axis as in drawn wire, and in the latter [112] is parallel to the axis as in rolled sheet.

Dr. A. Hargreaves described a moving film method of recording glancing-angle reflexions for a rotating sheet specimen; in this way the information necessary to draw almost a complete pole-figure for one set of planes can be obtained from one photograph, and Dr. Hargreaves has used it to show the double orientation in magnesium sheet.

In the evening of the first day of the conference, Dr. P. P. Ewald gave an entertaining account of the international development of crystallography. Being in the subject at its beginning, he was able to give personal recollections of most of the great men of the subject. He described the various meetings which have been held since the War of 1914–18 to discuss rational organization, and showed the undoubted influence that these meetings have had. He then discussed the progress of the subject in terms of the titles of books published, and concluded by a well-thought-out plan for the future.

REFORM OF SCHOOL MATHEMATICAL SYLLABUSES

A GENERAL meeting of the Mathematical Association, the first to be held since the outbreak of the War, took place at King's College, London, on April 12 and 13. The meeting attracted a large number of members; the president, Mr. W. C. Fletcher, took the chair during the first part of the meeting and Prof. E. H. Neville deputized for him later.

The afternoon session on April 12 was devoted to a discussion on possible changes in the mathematical syllabus for the various School Certificate examinations. The discussion was opened by Mr. C. T. Daltry, who outlined some preliminary work done by the Association in 1938 and went on to consider the alternative geometry syllabus recently introduced by the Cambridge Local Examinations Syndicate. The principal points in this syllabus are: (*a*) a reduction in the number of theorems to be proved; (*b*) a more definite fusing of geometry and trigonometry; (*c*) the introduction of more practical material from map reading, plan- and elevation-drawing, etc. Mr. Daltry advocated a similar type of reform in regard to algebra, where the reduction of formal manipulative work would leave time for more progress in graphs and functionality, and the possible introduction of the easiest parts of the calculus (as an optional subject). He further recommended the general adoption of the 'mixed-subject' type of examination paper, each paper to be divided into an easy section where accuracy might be the principal requisite, followed by a section in which a choice of questions should be given.

Dr. F. C. Powell gave an account of the circumstances leading to the introduction of the Cambridge alternative syllabus. After contrasting the mathematical and physical approaches to any subject, he stated that in this syllabus a physical approach to the teaching of geometry is contemplated. This has led to the retention of only those parts of geometry which are useful in developing applications and have a definite practical value, and to the rejection of parts of the work which, though interesting in themselves, have no bearing on such development. It is too early, he said, to make an exact assessment of the degree of popularity which the new syllabus will achieve, but the response so far has made it clear that teachers are very ready to welcome such changes.

An interesting discussion followed, in the course of which general agreement was expressed in regard to most of the points raised, though doubt was expressed by some members as to the advisability of introducing calculus at too early a stage.

At the conclusion of the discussion, four resolutions were proposed by Mr. G. L. Parsons. The first two of these, which were passed unanimously, were as follows:

(i) "This meeting of the Mathematical Association is in favour of a general revision of the syllabus in Mathematics demanded of candidates for the School Certificate examination."

(ii) "This meeting is in favour of a reduction in the number of theorems of which candidates are expected to produce a formal proof and approves of the general principle that the work in Geometry and Trigonometry should be more closely co-ordinated. A more extensive use of three-dimensional ideas and a more practical approach are also desirable."

The third resolution, which found only a few dissentients, was as follows: "This meeting considers that a reduction should be made in the amount of formal Algebra demanded and that the time thus saved should be given to the study of graphs and functionality."

A last resolution, passed by a substantial majority, read: "This meeting would approve the introduction of elementary Calculus, treated principally from a graphical angle, as an *optional* element in Elementary Mathematics papers".

The remainder of the proceedings on the first day were devoted to papers by Mr. W. W. Sawyer on "The Theory of Functions" and Prof. L. M. Milne-Thomson on "Harmonic Analysis".

The meeting re-opened on Thursday with a demonstration by Mr. C. W. Hansel of the use of an apparatus consisting of a large mirror mounted at 45° to the horizontal in the teaching of mathematics. This apparatus allows a class to get a clear view of diagrams and other objects placed in a horizontal plane. A paper on "Infinite Series for Fifth Formers", given by Mr. N. M. Gibbins, concluded the morning session.

The main discussion in the afternoon dealt with a new Higher Certificate mathematical syllabus, drawn up by the Science Masters Association assisted by a number of members of the Mathematical Association. The discussion was opened by Mr. E. H. Lockwood, who gave an account of the events which led to these proposals. He outlined the various levels aimed at in the syllabus, and explained how this syllabus could, by a certain amount of adjustment, be made to fit in with the syllabus required by potential mathematical scholars. In the minimum syllabus, which was planned for a five-term course, emphasis has been placed on calculus and the function idea at the expense of geometry; and elementary rotational dynamics at the expense of more elaborate statics. In the advanced section of the syllabus, the same ideas have been followed out, for example, by the preference of differential equations, determinants, vectors and complex numbers to the usual work on the geometry of conics.

Mr. A. E. E. Mackenzie continued the discussion on behalf of the Science Masters Association, giving some account of the general background and of parallel activities which are being pursued in relation to other branches of science. He referred to widespread criticism from various quarters of the level reached by science students. He considers that the fundamental cause of this criticism is the overloading of the syllabus. An important step in redressing this state of affairs has recently been made in the setting up of advisory committees containing representatives of the teaching associations and some of the examining bodies. These committees, including one dealing with mathematics, have recently approved various proposals with regard to the scholarship syllabuses, and it is hoped that a general co-ordination of the Higher Certificate syllabuses and the scholarship syllabuses will become an established fact.

Dr. F. C. Powell referred to the genuine feeling existing among university teachers that the time has come to make changes in co-operation with the schools. The new advisory committees would certainly prove valuable in this work. He proceeded to an analysis of some of the points where difficulty has been experienced in practice in making a 'clean joint' between school and university work, and welcomed the appearance of differential equations and other parts of the proposed syllabus which would help to eliminate these difficulties.

Mr. C. G. Nobbs reviewed the proposed syllabus in considerable detail and answered certain points raised by previous speakers. He showed how the syllabus has been developed logically from the idea of functionality, and how various parts of the usually accepted mathematical course have been omitted, not because they are not interesting or even useful, but because they do not fit in with this central idea. He referred to the omission of geometry as being occasioned principally by considerations of time. He hoped the syllabus would not prove too long and that members would give it a trial.

A large number of members took part in the subsequent discussion, which in the main favoured the new proposals, especially in the 'ordinary' part of the syllabus. A number of speakers referred to the question of undue length, especially for girls. The view was expressed that the advanced syllabus might be abbreviated by a reasonable system of alternatives.

The final paper of the meeting was given by Mr. W. Hope Jones, in his usual entertaining style, the subject being "More Mathematical Geography".

At the business meeting of the Association, Mr. C. O. Tuckey was elected president for 1944 and the other officers were re-elected. The Council's report showed that the Association has well maintained its membership and is in a sound financial condition. Reference was made to the excellent work of Prof. T. A. A. Broadbent in maintaining the standard of the *Mathematical Gazette* in spite of paper restrictions and other war-time difficulties. A full report of the proceedings will be given, as space permits, in that journal.

CONTROL OF TYPHUS

RECENT references in the daily Press to the appearance of typhus in eastern Europe have prompted a number of questions. What risk is there of outbreaks of typhus among British troops abroad, or of its introduction into Great Britain? What risks will there be of outbreaks of typhus in Europe after the War? Articles in the medical Press show that the whole problem of typhus is being considered all over the world; for typhus is always a serious matter, whether nations are at war or at peace.

At the present time, of course, British troops are contending with an outbreak of typhus in Naples, which has (*Brit. Med. J.*, Feb. 5, 1944, p. 205) become so serious that it is a potential menace to military operations. So far it is confined to civilians. Immunization by serum has been organized, and some 70,000 civilians a day are being treated for infestation with lice. The outbreak began under German occupation, and has increased since the German destruction of the gas and water supplies, and as a result of

overcrowding with refugees and others. It is evidently being vigorously attacked.

Some of the risks run by British troops in the Middle East are indicated by abstracts in the *Bulletin of War Medicine* and by an article by two R.A.M.C. officers, Lieut.-Colonel W. Brockbank and Major S. R. F. Whittaker (*The Lancet*, Jan. 29, p. 150). According to these authors, although the incidence of typhus is high among civilians in some parts of the Middle East, only sporadic cases have occurred so far among troops there. They describe ten cases, all of whom were British soldiers, which they treated between March and May, 1943. They direct attention to the fact that the early symptoms of typhus may be so like those of malaria, sand-fly fever, relapsing fever or typhoid that a diagnosis when the patient reports sick may be very difficult. The patient may stay for some days in a general ward in a hospital before the diagnosis can be made. Actually eight out of the ten cases described remained in a general ward until the rash of typhus fever appeared on the fifth or sixth day of the illness. The diagnosis was made more difficult by the fact that evidence of the presence of, or contact with, lice was present in only one of the ten cases. Fortunately, no cross-infection occurred. The mortality-rate from typhus is higher in patients more than thirty years old, so that the authors recommend that no personnel older than this should be detailed for duties likely to expose them to contact with typhus. Further, all personnel likely to come into contact with typhus are now given typhus vaccine. The efficacy of the typhus vaccines has been questioned, but Dr. J. B. Penfold, of the Emergency Pathological Service Laboratory, Billericay, reports (*Brit. Med. J.*, Jan. 22, 1944, p. 114) on tests made with a Cox vaccine prepared in Toronto from a European louse-borne strain of *Rickettsia prowazeki*. He vaccinated 23 public health workers with this, and found that the reactions to it were generally slight and local, and that vaccination produced an increase of the agglutination titres in most cases. Drs. Bardhan, Tyagi and Boutros, of No. 12 Field Laboratory, M.E.F., have reported (*Brit. Med. J.*, Feb. 19, 1944, p. 253) on the glass-slide agglutination test for the rapid diagnosis of typhus, modified by them for general use. They urge further trials of this method to establish conclusively the degree of its reliability.

Typhus risks in Europe are discussed by Dr. Yves Biraud, of the Epidemiological Service at Geneva (*Bull. Health Org. League of Nations*, **10**, No. 1; 1943. See *The Lancet*, May 15, 1943, p. 620, and the fuller abstract in the *Bulletin of War Medicine*, **3**, No. 10, 567; 1943). Dr. Biraud says that typhus has increased in Poland and the Balkans to a disquieting, but not to an alarming, degree since the outbreak of the War. Sporadic foci have also appeared in Germany and Hungary in areas which have been free from the disease; presumably these have been brought from the Eastern front. We may compare this with the outbreaks in German troops of another disease not prevalent in Germany before the War, namely, trichiniasis, which has occurred in Norway and on the Eastern front. Sporadic foci of typhus have also been found in central and southern France; but almost all the cases in these areas have been people arriving from North Africa, where the disease is always present. Bad economic conditions, such as those which resulted from the fall of France, increased its incidence in North Africa. It is not surprising that the incidence in 1941 was more than twice that recorded for any of the preceding twenty years, and that the 1941 figures were exceeded in the early months of 1942.

Typhus in Iran was the subject of an address by Col. Faruqi, I.M.S., to the recently formed Anglo-Iranian Medical Society (*Brit. Med. J.*, Dec. 25, 1943, p. 820). Last year, said Col. Faruqi, typhus killed many people and he feared a much more serious epidemic. He explained that there are plenty of medical men with wide experience of typhus now in Iran, but suggested the formation of a committee to control preventive work and to co-ordinate information.

In Spain the typhus epidemic of 1908–9 stimulated intensive study of the treatment and prevention of the disease. An account of the modern methods now being used in Madrid is given by Prof. Clavero del Campo, director of the National Institute of Health, and Dr. Perez Gallardo in a monograph entitled "Técnicas de Laboratorio en el Tifus Exantemático". This is an official publication of the Dirección General de Sanidad, Madrid, and was published in 1943. To it the director-general of health, Prof. J. A. Palanca, contributes an introduction which outlines the measures taken against these two epidemics and indicates the areas invaded by the disease. After the epidemic of 1908–9, he says, sporadic cases occurred in Spain until the epidemic of 1941–42 began. While it is as yet too early, he thinks, to claim that the latter epidemic has been conquered, it has been controlled. His account of the difficulties encountered and the measures taken shows that full advantage is being taken of the experience of specialists in other countries and of the experience gained by Dr. Gallardo when he was sent to laboratories in Germany, Poland and elsewhere. Such difficulties as the destruction by war of the National Institute of Health and the modern Rockefeller Virus Department might have daunted any but the most persistent and enthusiastic workers.

In another paper Prof. Clavero and Dr. Gallardo give the results of their work on a strain of *R. prowazeki* originally isolated and cultivated by the Cox technique on chick embryos by Dr. Snyder in 1941, and on a variant of this strain which has lost its pathogenicity, yet has retained its immunizing power (*Revista de Sanidad e Higiene Publica*, Madrid, June 1943). In further papers they report on their work on Giroud's intradermal test for typhus infection (*ibid.*, Dec. 1942) and on their investigation (*ibid.*, May 1943) of 384 rats and 62 fleas in Madrid, from which they conclude that a murine virus does not exist in the rats of Madrid. They discuss the errors which may arise from the presence in rats of various bacterial infections (*Salmonella enteritidis*, *B. alcaligenes broncho-septicus*, Spirochætes, etc.). We have already referred to the work of other Spanish medical men on typhus in some of the Latin-American countries: in Venezuela, for example (NATURE, Jan. 8, 1944, p. 51), and Bolivia (NATURE, Feb. 5, 1944, p. 162). The existence of endemic typhus in Bogotá, Colombia, is reported by Prof. Luis Patiño-Carmago (*Rev. de la Facultad de Medicina, Bogotá*, **11**, 503; 1943), who claims that eight strains of the Rickettsia type have been found in various parts of Colombia. The pages of this journal and of the *Boletin de la Oficina Sanitaria Panamericana* show that typhus is being carefully watched and combated throughout Latin and North America.

Finally, reference may be made to an annotation in *The Lancet* (May 1, 1943, p. 562) which discusses the precautions taken against the entry of typhus

into the British Isles. Control depends on the control of the head or body louse infected with *R. prowazeki*, on prompt isolation of patients and contacts, delousing, disinfection of both the premises of the patients and the contacts, and on other measures which can only be carried out effectively by specially trained personnel. These personnel must be themselves protected (by protective clothing, vaccination, etc.). In England such mobile anti-typhus squads were formed some time ago. The shortage of nursing personnel made it difficult to provide suitable people for this duty, because they must be young (see above); but plenty of volunteers were available. At the same time, many authorities earmarked suitable sections of isolation hospitals for possible typhus cases. Such measures as these, combined with the strict watch which is kept at ports of entry and on aeroplanes, indicate that the risk of the entry of typhus into the British Isles is not being neglected. G. LAPAGE.

FORTHCOMING EVENTS

Friday, April 28—Sunday, April 30

INSTITUTE OF INDUSTRIAL ADMINISTRATION (at the Waldorf Hotel, Aldwych, London, W.C.2). Conference on "Management and Society".

Saturday, April 29

BRITISH RHEOLOGISTS' CLUB (at the Shirley Institute, Didsbury, Manchester), at 10 a.m.—Discussion on "Elastic Behaviour of Textile Materials".

ASSOCIATION FOR SCIENTIFIC PHOTOGRAPHY (at the Caxton Hall, Westminster, London, S.W.1), at 2.30 p.m.—"Photography as a Tool in Agriculture" (Papers will be read by Dr. E. N. Crook and Mr. V. Stansfield, and by a Representative of the National Institute of Agricultural Engineering).

PHYSICAL SOCIETY (at the new Clarendon Laboratory, Oxford), at 2.30 p.m.—Prof. Joel H. Hildebrand: "The Liquid State" (Twenty-eighth Guthrie Lecture).

Monday, May 1

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. R. H. Bound: "Aircraft Hydraulic Equipment".

INSTITUTION OF ELECTRICAL ENGINEERS (CAMBRIDGE AND DISTRICT WIRELESS GROUP) (at the Technical School, Cambridge), at 5.30 p.m.—Mr. C. R. Stoner and Mr. R. W. Wilson: Discussion on "Training for the Radio Industry".

Tuesday, May 2

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield 1), at 6.30 p.m.—Mr J. S. Ridges: "The Work of the Iron and Steel Control".

Wednesday, May 3

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.15 p.m.—Silver Jubilee Commemoration Meeting.

Thursday, May 4

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. L. G. Grimmett: "The Electrostatic Generator, its Development and Prospects".

INSTITUTION OF ELECTRICAL ENGINEERS (INSTALLATIONS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. W. N. C. Finch and Mr. F. Lynn: "The Design and Performance of Domestic Electric Appliances".

Friday, May 5

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. A. S. Kennard: "The Crayford Brickearths".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN THE MECHANICAL AND CIVIL ENGINEERING DEPARTMENT—The Registrar, Technical College, Sunderland (May 5).

SECRETARY (temporary) of the Department of Agriculture—The Acting Registrar, The University, Leeds 2 (May 6).

Permanent BIOLOGIST (male or female) in the Public Health Department—The Medical Officer of Health, Town Hall, Luton (May 8).

EDUCATIONAL PSYCHOLOGIST (full-time), and a PSYCHIATRIC SOCIAL WORKER (full-time)—The Director and Secretary, Education Offices, Brettenham Road, Edmonton, London, N.18 (May 8).

TECHNICAL OFFICER to advise on questions of cropping and manuring of arable land and the management of dairy stock—The Secretary, Berkshire War Agricultural Executive Committee, 1 Abbot's Walk, Reading (May 8).

LECTURER (full-time) IN ELECTRICAL ENGINEERING at the Lancaster Technical College—The Director of Education, High Street House, Lancaster (May 8).

PRINCIPAL OF THE BLACKPOOL AND FYLDE TECHNICAL COLLEGE—The Director of Education, 3 Caunce Street, Blackpool (May 8).

DRUMMOND PROFESSORSHIP OF POLITICAL ECONOMY—The Registrar, University Registry, Oxford (May 13).

UNIVERSITY READERSHIP IN CHEMICAL PATHOLOGY tenable at University College Hospital Medical School—The Academic Registrar, University of London, at Richmond College, Richmond, Surrey (May 15).

LECTURER IN SCIENCE AND ELEMENTARY ENGINEERING SUBJECTS—The Principal, County Technical College, Worksop, Notts. (May 15).

ENGINEERING INSPECTOR OF MINES (temporary) in a Government Department—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.2088A) (May 17).

W. H. COLLINS PROFESSORSHIP OF HUMAN AND COMPARATIVE PATHOLOGY—The Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2 (July 31).

SENIOR LECTURESHIP IN THE DEPARTMENT OF METALLURGY of the University of the Witwatersrand—Dr. W. Cullen, 4 Broad Street Place, London, E.C.2 (July 31).

CHIEF ENGINEER AND GENERAL MANAGER of the Gloucester Electricity Undertaking—The Town Clerk, Guildhall, Gloucester.

GRADUATE LECTURER IN ELECTRICAL ENGINEERING at the Southend-on-Sea Municipal College—The Chief Education Officer, Education Office, Warrior Square, Southend-on-Sea.

LECTURER (full-time) IN MATHEMATICS—The Registrar, Municipal College, Portsmouth.

LECTURER (temporary) in MECHANICAL ENGINEERING—The Principal, Handsworth Technical College, Golds Hill Road, Handsworth, Birmingham 21.

PHYSICIST to the Newcastle-upon-Tyne National Radium Centre—Dr. A. W. Sanderson, Secretary of Newcastle-upon-Tyne National Radium Centre, Royal Victoria Infirmary, Newcastle-upon-Tyne.

SCIENTIFIC RESEARCH IN GREAT BRITAIN

SCIENTIFIC workers have every reason to regard the debate in the House of Commons on April 19 on Sir Granville Gibson's motion calling for a bold and generous Government policy towards research with as much satisfaction as Mr. Attlee's encouraging reply. The debate itself ranged over a wide ground, and no scientific worker could desire to have so many of his points made more effectively or trenchantly than was done in its course. The case for adequate remuneration of the scientific worker was pressed even more forcibly than in the House of Lords debate last July, and the arguments on this point of Sir Granville himself, Mr. E. W. Salt, Mr. Edmund Harvey, Mr. J. Griffiths, Mr. Owen Evans and Captain Plugge, who touched also on the broad question of incentives, would have seemed incredible in a Parliamentary debate ten or twenty years ago.

The credit for this change of outlook must be attributed in no small measure to the work of the Parliamentary and Scientific Committee, the reports of which have done much to prepare the ground for the debate. It should be noted, however, that other recent reports dealing with scientific and industrial research, notably that from the London Chamber of Commerce, have tended to stress the importance of adequate remuneration if we are to attract men of outstanding ability to a career of scientific or industrial research, and the direction of such research. The note was equally prominent in the series of addresses on "Science and Industry" recently arranged by the Manchester Chamber of Commerce, and after Mr. D. Owen Evans's emphatic comment on the comparative salaries offered for research directors in the Government service, Mr. Attlee gave the assurance that the whole question of the payment of scientific men in Government service in relation to other Government employment of similar status is under consideration, and that already steps have been taken to raise the remuneration of the heads of research institutions.

The point is worth noting, less for its intrinsic importance or prominence in the debate, than as showing the measure of the progress made in recent discussions. The disposition to accord due status to the scientific worker is a factor the importance of which in recruitment and expansion of the ranks of research workers is not easily overstressed. Incidentally, it bears on the organization of the two-way traffic and constant interchange of workers to which Sir George Schuster and also Air-Commodore Helmore both referred in the debate. There are, as Sir George indicated, difficulties in arranging such interchange between research workers in the universities and in industry; but whether or not a special inquiry, as suggested by Sir George, by a committee of university workers and industrialists is required, the establishment both in industry and in the universities of attractive, equable and comparable conditions of remuneration, status and service would remove one formidable obstacle to interchange.

That the importance of status and conditions of service of the research worker should receive recognition in this manner is the more encouraging because the whole spirit of the debate in the House of Commons showed an appreciation of the prime importance of establishing the conditions which not only attract first-class minds to research but also are conducive to creative work. Any idea that the value of research can be measured by the payment made to the research worker was as flatly squashed by Dr. Haden Guest as the idea that research results can be obtained to order was dispelled by the speeches of half a dozen members. Again, the importance of freedom of research work and of the freedom of the whole life of the universities was very well put by Mr. Edmund Harvey and by Mr. Griffiths, and the references to the operation of patent law were obviously prompted by a like concern to secure conditions in which fundamental research could be developed in complete freedom, and that knowledge made available as a result of public expenditure on industrial research should be used for public and not for private ends.

In the tributes paid to the achievements of research workers in Great Britain during and indeed before the War, and also in the refusal to regard quantity as more important than quality when British research effort is compared on a numerical basis with the research effort of other countries, and notably that of the United States, it was clear that members of the House of Commons realize that these factors of status, remuneration and conditions of work are all-important through their direct bearing on the research worker himself. In the expansion of research, whether in industry or at the universities, the personal factor is rightly put first, for unless the requisite quality is there, no amount of organization will enable us to overcome some of the handicaps under which we are placed in Great Britain, or to make the most of such advantages as we may possess.

This agreement on the prime importance of quality in the research worker himself was accompanied by equally emphatic agreement that, in the main, the fundamental research on which progress ultimately depends must be the task of the universities. For this purpose alone, expansion of the universities to meet the post-war situation is imperative; but it is equally imperative to expand the teaching side so as to provide industry with the increasing number of scientific workers required, and, urgently, to be ready to re-train for careers in science and in research men from the Forces who will be released by demobilization. The extent of this expansion is a matter for discussion, but there is already a large measure of agreement that the present annual grant to the universities of Great Britain should be doubled or trebled at an early date, and that capital expenditure of some £10,000,000 will be required over the first five years following the War, and possibly double that figure in a long-term policy. Mr. Attlee, in his reply, made it quite plain, without committing himself to figures, that the Government recognizes there must be much greater expenditure both on fundamental research and on teaching at the universities.

With this general measure of agreement went a further consensus of opinion that adequate provision has not yet been made for continuing in times of peace the fruitful collaboration between science and industry which has contributed so much to the war effort. That was the central question raised by Sir Granville Gibson in moving his resolution, and the evidence that the present position is not regarded as satisfactory is to be found in the suggestions which came from all parts of the House as to the scope of that effort, the organization or co-ordination of our research effort itself, and finally the means by which the effective utilization of results in production can best be secured.

First, as regards scope. Mr. E. W. Salt, who referred in particular to the report of the Parliamentary and Scientific Committee on coal research, emphasized the opportunities which await intensive scientific research in this field; he was strongly supported by Mr. Owen Evans, who put in a powerful plea that our industrial research should be directed to the industrial processes which exist in Great Britain, to the discovery of new industries, and especially to the utilization of raw materials which exist at home and in the Colonial Empire. In particular, he stressed the inadequacy of our geological surveys both at home and in the Colonies. In this plea he was followed by Mr. James Griffiths, who urged the necessity for central direction from the Government if we are to make the fullest use of existing scientific knowledge on the utilization of coal and build upon it a new integrated industrial structure.

Agricultural research in its broadest aspects found equally strong support. The expansion of our research effort in such fields as animal diseases and nutrition, food and nutrition, soil fertility, and biology, including fisheries, was repeatedly urged, and though the formation of an Economic and Social Research Council to take its place by the side of the Agricultural and Medical Research Councils and with the Department of Scientific and Industrial Research was not specifically mentioned in the debate, this vital group of human studies was clearly present in members' minds, as was shown in Mr. Shepherd's plea for research into distributive costs.

The unevenness of the present front of both scientific and industrial research was thus well brought out in the debate, and it was natural that there should be considered the further question as to the ways and means by which this can best be remedied. For the most part, the question as to the means by which some co-ordination could be effected in the expansion of the universities was that with which members were concerned. Mr. Price expressed the opinion that it would be better to bring the machinery responsible for giving grants to the universities more directly under the office of the Lord President of the Council, who already has the Department of Scientific and Industrial Research under his wing. This was one of the points considered in the report of the London Chamber of Commerce, although the committee responsible reached no decision as to whether or not the suggested central research board should be responsible for allocation of grants to the

universities for research. What Mr. Price had chiefly in mind, however, appears to have been that the right point of view is more likely to be represented if the machinery is handled by the department of the Lord President of the Council than by the Treasury.

Mr. Harvey suggested that it would assist, if not the University Grants Committee, at least the work of the universities, if there were formed an advisory council for the universities, to allow for the interchange of experience, for the development of work in harmony in different parts of Great Britain, the prevention of overlapping and the discussion of arrangements for new chairs for new subjects, so that money will not be squandered by three or four universities trying to start a new chair in a particular subject when one university would be sufficient if the effort could be concentrated. This suggestion was dismissed a little summarily by Mr. Attlee, but those who have advanced the idea of a universities advisory council are at least as aware as Mr. Attlee of the tenacity of the universities in regard to their independence and individuality, and of the practical difficulties of establishing any such body. In this connexion the proposal for the formation of a joint standing council of representatives of the University of Manchester and the Chamber of Commerce might have potentialities for university co-operation as well as for co-operation between science and industry.

To dismiss the suggestion without any constructive proposal as alternative is going too far at the present time. However generously the Government may be disposed—and able—to augment the grants for teaching and research at the universities, the best use cannot be made of the money available unless it is distributed in accordance with some definite plan based on national needs and not those of individual universities or even of regions. Sir Ernest Simon's recent pamphlet affords decisive support on this point for such criticism of duplication and waste as is to be found in "Redbrick University", for example. It should not prove an insuperable task to recast the functions and powers of the University Grants Committee to provide the essential machinery for such co-ordination if the establishment of a new body is inexpedient. Beyond this, there is the question of new universities and of the expansion of the technical colleges to university status—a question which should be considered from a national point of view.

Another suggestion, ventilated in the debate by Mr. Wootton-Davies, was that fundamental research should be organized by some sort of parliament of science—that universities should be represented on some sort of committee or parliament, with some directive force such as a Minister of Science to direct it. This suggestion also was rejected by Mr. Attlee ; but while he rightly said that we need in all departments persons who are trained in the scientific method and appreciate what it means, as well as departmental research, he again failed to deal constructively with a proved need for co-ordination.

If, as Sir Granville Gibson said, it is necessary to plan the application of science to industry, it is no less necessary to plan, not in detail but broadly, the whole of research. The allocation of the Government grant to research as between industrial, agricultural, medical and other research, and pure and applied research, should not be haphazard but planned in accordance with national needs. This was Dr. Haden Guest's argument for making permanent the Scientific Advisory Committee of the War Cabinet.

To Dr. Haden Guest's suggestion that the Scientific Advisory Committee should be asked to prepare a plan for the development and carrying on of scientific research for a ten-year period, Mr. Attlee made no reply ; but in regard to the means by which the effective utilization of research in industry can be secured, his attitude was more reassuring. On this question Sir George Schuster's contribution to the debate was the most important. He emphasized three things : the necessity of creating a more scientific frame of mind in British industry—which means many workers trained in science and a rapid development in all forms of scientific and technical education. Secondly, the closer contact between those engaged in scientific research and those concerned with its practical application—the two-way traffic already referred to ; and thirdly, the discovery of further means of assisting the stage of development and the practical evolution of new industrial ideas. While deprecating some of the comparisons made with the United States, Sir George said that we have much to learn from them ; in particular he referred to the Mellon Institute and its system of industrial fellowships as a method worth consideration by the small firms of Great Britain.

On this point Mr. Attlee stated that the Government recognizes the need for the establishment of some fund to meet the cost of developing new inventions and of providing facilities for testing new ideas for industry. The best way to meet this need and to fit it in with the work of the research associations is now under examination. Mr. Attlee was also careful, however, to point out that Government support for research must be backed by a readiness to use the results of that research. There must be receptive minds in those responsible for the conduct of industry and in the general public. Although the Government can do much to stimulate research, the main responsibility for applied research must continue to fall upon industry itself, and in many industries this is less a question of further expenditure than of assigning to research its proper part and status in the organization.

The personal encouragement scientific workers may well derive from the debate should stimulate them to further efforts in the task of education, no less than to determined thinking about the many difficult problems of organization and co-ordination on which the debate also touched. Certainly there could not have been put into their hands a more convincing demonstration of the dependence of a permanent increase in agricultural and industrial productivity on scientific research, on the speedy application of its results and the training and skill of the working population. The whole nation, as well as industry, must be roused to go forward adventurously and with faith in its future, to seize the opportunities in the post-war world which are so clearly within its grasp.

TAXATION AND RESEARCH EXPENDITURE

A FEATURE of recent reports on industrial research has been the emphasis which has been placed on the influence taxation is capable of exerting upon research expenditure. The Federation of British Industries, for example, has advanced the principle that all expenditure on research and development should be chargeable against revenue, either immediately or over the commercial life of any asset created. This principle was strongly endorsed by the Industrial Research Committee of the Federation, which in its report last autumn referred to the deterrent effect on the expansion of research of any narrow interpretation of what is allowable expenditure for taxation purposes. The London Chamber of Commerce, expressing its agreement with this view, urged further that the cost of pilot plant, as well as of laboratory buildings and equipment, should be made chargeable against equipment. The question has been further examined by the Parliamentary and Scientific Committee, which in a memorandum on Taxation and Research examined the present position and instanced some of the defects of the present system. This memorandum was based on the ideas first that in modern conditions no industry can maintain its competitive position unless it devotes adequate effort and money to scientific and industrial research. This applies with special force to British industry, having regard to the conditions and tasks which will confront it after the War. Secondly, the money required for such research will be substantially greater than in the past. Again, judged by standards in other industrial countries, and quite apart from its own exceptional needs, British industry has in the past devoted far too little effort and money to scientific and industrial research; and lastly, an increase in the productivity of labour, which is one of the main consequences of industrial research, is a vitally important factor in making possible an improvement in wages and social services. The recent debate in the House of Commons on Government provision for research showed that these ideas are widely shared.

The memorandum went on to urge that every impediment to the undertaking of scientific and industrial research by British industry should be removed and inducements provided to stimulate progress. In particular, the memorandum recommended that the law relating to the taxation of profits should be amended so as to recognize the principle that all expenses incurred on research and development are allowable as deduction from taxable profits, with the corollary that receipts from a lease or sale of discoveries should be brought into taxable profits. Expenditure on research which creates a tangible asset with a measurable life, and expenditure on the purchase of patents and processes, should be similarly allowable over a period of years. All other expenditure should be allowable in the year when it is spent. No distinction should be made between pure research and applied research and development. A special writing-off allowance on capital assets provided solely for research purposes was also suggested, as well as the increase of depreciation rates for industrial buildings and plant to include obsolescence by an arbitrary addition to the rates allowed for wear and tear.

Sir John Anderson went far to meet these proposals in his Budget speech, which may well be regarded as something of a landmark in this respect. Recognizing first the supreme importance of appropriate allowances for capital expenditure in relation to reconstruction to enable British industry to meet the post-war challenge, he proposed a special allowance of 20 per cent of the cost of new plant and machinery, and as a part of post-war policy that the obsolescence allowance should be given when plant and machinery are scrapped, whether the particular piece of plant or machinery is replaced or not. With regard to buildings such as factories and buildings associated with them for welfare purposes or storage, he proposed an annual depreciation allowance of 2 per cent with an initial allowance of 10 per cent as an immediate instalment.

Referring to scientific research, the Chancellor of the Exchequer believes there is a case for modifying the distinction drawn for income-tax purposes between capital and revenue expenditure on research. He therefore proposes that any research expenditure of a capital nature, including expenditure on laboratory buildings, plant and machinery, should be allowed for a period of five years, or for the life of the asset, whichever is the shorter, as a deduction from profit for income-tax purposes. Further, any payment, whether for capital purposes or not, made by a trader to a central research body approved by the Department of Scientific and Industrial Research, should be allowed as and when made as a deduction in computing the profits of the concern.

Sir John Anderson, after observing that we should not depreciate our own efforts in the field of research, went beyond these proposals to relieve from taxation funds devoted to research, and expressed the hope that there would be much wider pooling of ideas in the field of research, and that the industrial research worker should be encouraged to regard himself not only as a servant of the organization which pays him, but also as a contributor to the sum total of available knowledge. Referring to chemical industry and the extraction of products from oil and coal, where plastics is only one of the fields opened up, he said that there should be no obstacle placed in the way of chemical industry in obtaining raw materials from oil. He was not prepared to place scientific proposals before Parliament at the moment, but proposed to arrange with the Minister of Fuel and Power for an inquiry to supply the data required for specific proposals.

Following so swiftly on the debate in the House of Commons on Sir Granville Gibson's motion on April 19 (see p. 539), the Chancellor's speech should give the liveliest satisfaction to scientific workers. His speech, no less than his proposals, leave no room for doubt as to the importance the Government attaches to research, or its appreciation of the contribution scientific workers have made to the war effort. That

such proposals and recognition should find so prominent a place in the Budget speech affords firm ground for the hope that scientific workers will be given a full opportunity to play their part in reconstruction, and that the Government is determined to establish the conditions in which scientific and industrial research may make the largest possible contribution to the progress and well-being of the nation.

RHEOLOGY: PRACTICAL AND THEORETICAL

Ten Lectures on Theoretical Rheology

By Dr. Markus Reiner. Pp. iv+164. (Jerusalem: Rubin Mass; London: H. K. Lewis and Co., Ltd., 1943.) 22*s*. 6*d*. net.

A Survey of General and Applied Rheology

By Dr. G. W. Scott Blair. Pp. xvi+196. (London: Sir Isaac Pitman and Sons, Ltd., 1944.) 18*s*. net.

RHEOLOGY probably owes much of its appeal to the fact that it has not yet developed into a fully established science with a generally accepted subject-matter and method of treatment. The study of the "flow and deformation of matter" might include almost anything in Nature, and indeed there are few industries in which problems essentially rheological in character do not arise. These problems frequently have to be attacked by chemists, physicists or engineers whose training has provided them with only a very meagre basis on which to work, and the appearance of two books on rheology by two of the best-known pioneers in this field will be especially welcome to them.

The two authors approach their subject at very different angles. Dr. Reiner, taking the point of view of the mathematical engineer, develops his subject by methods of the kind with which we have become familiar in the classical theory of elasticity. He says, in effect, "These equations represent possible types of behaviour of matter; let us see whether we can find materials which behave accordingly". Dr. Scott Blair, on the other hand, sets out from the experimentally observed rheological phenomena (of which he possesses an encyclopædic knowledge), tries to find equations to represent the data, and hopes that an explanation may emerge.

Dr. Scott Blair shows us that the essence of a rheological investigation is the determination of the relation between the three variables, stress, strain and time. Starting from a consideration of the two extreme 'ideal' materials, the Hookean elastic solid and the Newtonian viscous liquid, he leads up to the discussion of those more complex materials (which are the special concern of rheology) for which both the amount of strain and rate of straining vary with time, under constant applied stress. Such materials combine some of the characteristics of both the solid and liquid states. Altogether there are at least nine main types of deformation (or flow), which are presented in the form of a table, but this is not considered to be exhaustive. Thixotropy, dilatancy, plasticity, false body and a number of other rheological phenomena are discussed in detail, and particular attention is paid to the question of definition of the terms employed. The book contains a full discussion of the significant information to be sought in a rheological investigation, and a critical examination of the experimental methods available. A valuable feature is the inclusion of a comprehensive collection of references, carefully arranged and annotated. (But why Roman numerals for volume numbers ?)

In the second part of the book Dr. Scott Blair deals with a subject which has so far received comparatively little attention by rheologists, namely, the very important practical question of the relation between physical measurements and psychological judgments. The problem confronting the rheologist in industry is to find quantitative methods of assessing properties which the skilled craftsman is in the habit of judging by thumb-and-finger methods. The concepts entering into the judgment are usually mixed, and seldom consciously appreciated. The situation is very well illustrated by the concept of 'firmness', which has been the subject of a special investigation by the author and his collaborators. From the results of this investigation one is forced to conclude that the concept of firmness is not based on a mental analysis of perceptions into concepts of the kind with which ordinary physics deals, such as, for example, average applied force or total strain. The judgment appears to be a direct reaction to the total situation, in which all the relevant components are appreciated as a single integrated pattern or *Gestalt*. Here one is in danger of becoming involved in the philosophical mystery of the relation between the conscious perceiving mind and the external (?) perceived universe. But without going so far, one must recognize that Dr. Scott Blair has brought out the rather fundamental difficulty of what might appear at first sight to be a straightforward problem in rheology, and this presentation of his unique experiments will be generally welcomed.

Dr. Reiner begins his "Lectures" with an analysis of stresses and strains, using tensor notation. He develops the conception of a general rheological equation relating stress and strain and the time-derivatives of these variables. By suitable choice of the terms of this equation, special cases are obtained which represent possible types of rheological behaviour. Arranging the types in order, we have at one end the Euclid (incompressible and undeformable) solid. Then follow the Hookean (ordinary elastic) solid, and the Kelvin (viscous) solid, in which the elastic deformation is subject to a time lag. At the other extremity we have the Pascalian (incompressible non-viscous) liquid, the Newtonian (viscous) liquid, and the Maxwell (elastic) liquid, in which the stress decays with time. The properties of these types are discussed, and compared with actual materials. The intermediate region contains the more complex types, some of which are discussed in detail. The table may be compared with the rather similar table of deformations given in Dr. Scott Blair's book.

A number of special problems are considered, including, in particular, the theory of breaking. It is shown that a Kelvin solid breaks when the *strain* reaches a given value, while in a Maxwell liquid failure occurs at a critical value of *stress*.

It would appear that in respect of purely elastic strains, the tensor methods used in this book are applicable only when the strains are small. Many rheologists would like to know what methods to apply in the case of large deformations.

Both the works under review, which are in a sense complementary, should be studied by all who are interested in rheology. L. R. G. TRELOAR.

THE ART OF THE OPTICIAN

Optical Workshop Principles

Being a translation of "Le travail des Verres d'optique de Précision", by Col. Charles Dévé. Translated by Thomas L. Tippell. Pp. xiv+306. (London: Adam Hilger, Ltd., 1943.) 20*s.* net.

IT may at first sight seem surprising that a second book on the grinding and polishing of lenses should have been published by Hilger's so soon after their publication of "Prism and Lens Making" by Mr. Twyman. But there are at least two reasons which justify such a course. In the first place, lens-making is a craft, and each craftsman's account of his experience has something of value to every other craftsman. In the second place, the author is a Frenchman, and it is much to be desired that information about the techniques employed in one country should be made available in other countries. It is a novel experience to find the names of pioneers turn out to be names of Frenchmen rather than Britons, while the sources of specially suitable material or apparatus are quoted as French rather than English.

The book is based on the instruction given at the Institute of Theoretical and Applied Optics, Paris, to students of optical glass-working, and Part I is specifically addressed to working opticians. Part II is of a somewhat more advanced character and is intended primarily for works managers and senior workmen engaged in the supervision and direction of high-grade optical work. There is a great deal of useful information in the various sections, from recipes for cements and details about abrasives and polishers to methods of testing by interference and otherwise and to processes of etching, silvering and so forth. But by far the most important part of the book is concerned with the mechanical problems involved in producing a surface of given shape and curvature.

It is no easy matter to evaluate the relative effects of the different motions, rotational and translational, of either the tool or the work on the shape of the surface being ground, yet without some knowledge of the underlying principles, the average workman may easily go astray when he is put to a novel or unaccustomed task. The chapters dealing with the production of spherical and cylindrical surfaces, the effect of the size of tool, the pressure to be exerted, the surfacing of lenses of deep curvature, retouching, thermal deformations, working of metallic mirrors and so on, which include several theorems regarding the distribution of wear under various conditions, are a valuable contribution to the art of lens-making. An unusual, though not unwelcome, feature in a book of this type is the inclusion of a number of exercises to demonstrate the application of the principles which have been described.

It is somewhat surprising to find that the author has not dealt to any serious extent with the nature of the action of the abrasive on the surface of the glass during grinding and polishing. Even if the actions of the workman cannot be adjusted to modify the character of a ground or polished surface, it would have been interesting and instructive to learn whether the author considers, for example, that the polish on a surface arises from thermal flow or from extremely fine abrasion.

The translator is to be congratulated on his English rendering of the text, and on the useful vocabulary of French technical terms with their English equivalents. The footnote which he has added as a correction on p. 224 is itself in error; but in general the book would seem to be commendably free from mistakes.

As the translator remarks in his foreword, it was unfortunate that owing to the War the author and translator were not able to exchange ideas, as this might have allowed for the omission, or amending, of one or two passages which to an English reader may well seem too simple and naïve; this would apply, in particular, to the opening paragraphs of Chapter 1. But without the author's authority any such amendment would obviously be unwarranted.

W. D. WRIGHT.

WATER PURIFICATION

The Purification of Water Supplies

By George Bransby Williams. Pp. 95. (London: Chapman and Hall, Ltd., 1944.) 7*s.* 6*d.* net.

THE appearance of a book on the purification of water supplies is most opportune at the present time when it is generally realized that all is not well with the water supply of Great Britain, especially the supply in rural districts, and when it is recognized what an important part water will have to play in the reconstruction problems with which the country is faced.

The author has attempted too much in too short a space. He has, in less than twenty pages, attempted to give a review of the principles of chemical science as evolved from the time of the Egyptians thousands of years ago, through Grecian, Roman and Arabian knowledge to the work of the Curies and of J. J. Thomson and Rutherford on the electronic structure of the atom. Such an attempt might well have proved disastrous; but not so in this case, and a readable chapter has resulted.

The book is arranged in eight chapters, each dealing with one or more aspects of the material considerations which arise in order to render a natural water fit for human consumption. These various aspects are enumerated rather than explained, and the experience of American and Indian practice is drawn upon very largely, while the accumulation of knowledge acquired by British practice is drawn upon to a less extent.

The chapter dealing with colloidal matter in water can only be described as sketchy, and in the chapter dealing with chemical precipitation the theories of coagulation and flocculation are inadequately explained.

The book serves a useful purpose in directing attention to the various points which must be considered when subjecting water to purification processes, and in stressing the fact that efficient scientific control of all operations connected with purification of water supplies is essential. Water purification is not a matter for the amateur, but is a subject which deserves far more co-operative attention from the engineer, the chemist and the biologist than it has received in the past.

A more careful proof-reading would perhaps have added to the value of the book. For example, Fig. 4 on p. 52 should have referred to the "accelator" type of water softener and not to the "accelerator" type; sodium bisulphide (p. 76) is not used for dechlorination, but sodium bisulphite has been so used. It would have been possible to make a better selection for the eleven illustrations in the text.

H. T. CALVERT.

THE WELLCOME–MARSTON EXCAVATIONS AT LACHISH, PALESTINE*

By OLGA TUFNELL

THE broad purpose of archæology is to increase our view of history. The field archæologist works for the historian; together they try to extend our line of vision, to indicate fresh points of view and fields of inquiry, and to sketch in the background and elaborate the detail of the known historic scene.

We owe our knowledge of Egyptian and Mesopotamian history almost entirely to recent archæology, but the history of Palestine has been preserved for nearly four thousand years, and is a unique means of control for archæological data, which can be checked against Biblical tradition.

The geographical position of Palestine makes it a land bridge connecting Asia and Africa. Many people left traces of their passage and assimilated something of the countries they passed through. Experience has shown that, if we are to assess cultural connexion or influence, style of decoration is more reliable than form or technique. Shape and method can be re-invented, but style is an æsthetic expression which in its less primitive stages shows marked individual characteristics. Thus the potsherd is sometimes more important than the palace, but all material remains add something to the perspective of the past.

With these thoughts in view, it was the intention of the expedition which became the Wellcome–Marston Archæological Research Expedition to the Near East to tap the lines of communication across the land bridge at strategic points, and to follow them in whatever direction they might lead.

Sir Henry Wellcome with Sir Charles Marston, Sir Robert Mond and Mr. H. D. Colt first considered the choice of a site in 1932, and the possibilities were discussed with Mr. J. L. Starkey, who became director of the Expedition, which set out in the autumn of that year. The choice of a site as a control point is influenced by practical considerations, water supply, accessibility, expense, quite as much as by geographical position and historic importance. Among the sites considered, Tell ed Duweir seemed to fulfil the requirements, though the soil was much encumbered by heavy limestone blocks, and the area of eighteen acres obviously required many years of systematic work. The promoters of the Expedition did not hesitate to undertake the task, trusting in Mr. Starkey's great abilities.

It is immaterial whether or not Tell ed Duweir can be definitely identified with Lachish. Its central position in the Shephelah, on the main Gaza–Hebron road, between Gaza and Jerusalem, shows that it must have been an administrative town of importance throughout its long history from the Early Bronze Age—say about 3000 B.C.—to the Persian conquest about 400 B.C. The lack of Greek and Roman remains facilitates excavation and was apparently due to a reorganization of the road system when the point of intersection of various routes was shifted to Beit Jibrin.

The Early Bronze Age appears to have been the most flourishing era at the site chosen. The extension of a limestone ridge, surrounded on three sides by valleys, which later became a 'Tell' or mound through the accumulation of debris, was already occupied. The circle of adjoining hills and the lower slopes of the mound were thickly pitted by caves, artificially enlarged, where a troglodyte population lived and traded outside any line of defence which may have existed on the crest of the ridge itself. The extent of the area covered by these dwellings is approximately 200 acres; so vast a centre of early life is unusual in Palestine, and the contents of these caves are easily exposed, in contrast to the stratified levels on the mound, which are below 45 ft. of town deposit. In order to obtain a connected view of events, as illustrated by the sherds, two sections were examined. The lower 10 ft. at the north-east corner probably date from the fourth millennium, and could reveal much that is new and foreign to local culture.

Some hundred and fifty pottery forms have been drawn and recorded from the cave dwellings, and they should add their quota to the steadily increasing knowledge of the Early Bronze Age, in which four distinct phases can now be recognized.

In common with observations from other sites, we note a tremendous cleavage in cultural affinity at the beginning of the Middle Bronze Age at Tell ed Duweir. The people dwelt in houses and built walls around them; the caves were often used as burial places. There is a total change in pottery technique, and a marked increase in the use of copper, which had already made an appearance in the transitional stage—only represented at Tell ed Duweir by a series of poorly furnished tombs. Scarabs were added to the equipment of the dead, and among the daggers one was found to be inscribed. Apart from many incised marks on Early Bronze Age pots, this is the earliest inscription yet found at Duweir, and it is close to the Sinaitic script associated with the origin of the alphabet.

For the first time, a system of defence became necessary, either against the dissatisfied remnants of the previous population, or against further newcomers of the invaders' kin. So far as we know, the earliest method of defence at Tell ed Duweir (though excavation may reveal an earlier one) consisted of a fosse some 8 m. broad, cut in the limestone, while the material taken from it was piled against the natural scarp of the mound to form a slope or glacis. It has been examined at the north-west corner of the mound, where the slope was cut into by the Iron Age city wall. But it was a fortunate position, for after clearance of the packing, a small oval grave was discovered, cut into the native rock. The body was immature, and the group of pots and bowls were all distinctive types. The position of the grave, and its relationship to the layers of thrown limestone from the excavation of the fosse, leave no shadow of doubt that it preceded this engineering work by some years.

Since Sir Flinders Petrie's excavations at Tell el Yehudiyeh, a small fort to the east of the Nile Delta, where he first discovered fosse and glacis fortifications, it has been assumed that the people who built them were also responsible for a particular kind of black pricked ware and 'button-base' juglets found at the site. The people known as 'Hyksos' or 'shepherd kings' set up a foreign dynasty in Egypt lasting about two hundred years, towards the end of the Middle Bronze Age. On comparing the evidence from Tell

* Substance of a Royal Institution discourse delivered on February 18.

Fara, south of Gaza, it is significant that in the graves of the period no button-base flasks were found, either of the red burnished or black pricked ware, though the typical fosse and glacis defences existed.

As Mr. Starkey pointed out in 1933, there is some further evidence provided by a decorated pot, found with a mass of other pottery on bedrock in the fosse. It is therefore undoubtedly later than the oval grave and the fortification. The decoration compares with similar motives, notably the bird and fish, from other sites in south Palestine and in Syria of the same period, about 1600 B.C., and the style of drawing in both areas is similar.

Prof. Speiser, in his account of excavations at Tell Billa on the Orontes, has directed attention to the duplication of the whole repertoire of decorative motives found at this period in Palestine in level 4 of his site. In addition, the cuneiform correspondence from Tell el Amarna, and Ta'annek in Palestine, reveals the presence of governors and officials with names of non-Semitic origin, belonging to the dialect used by this Hurrian people from north-east Syria. Prof. Speiser suggests that the Hurrians as represented at Tell Billa (3) were conspicuous among the later 'Hyksos' groups. They were possibly the dominating class in Palestine before the Hebrew invasion, and if so, it would account for the loyalty of some of Egypt's local governors, during the troubled times which are so dramatically described in the Tell el Amarna letters.

It seems that we are gradually acquiring the facts in south Palestine which will enable us to differentiate between the influence of the so-called 'Hyksos' people and that of the non-Semitic Hurrians, who figure so largely in the ethnic movements north of Palestine in the second millennium.

The relationship between the Yehudiyeh pricked ware, the fosse and glacis, and the three structures of the Fosse Temple (the contents of which were published in a volume of that name in 1940) will assist in this intricate problem. The actual position of the temple on the disused fosse emphasizes the intrusive nature of the cult, and we have yet to discover the earlier centre of worship, which presumably occupied a prominent position on the mound.

A point which links the Fosse Temple cult to that of the Hebrews in the following century is that the sacrificial bones found in the structures were almost exclusively those of the right foreleg; sheep (or goat), ox, and two wild beasts, gazelle or ibex, were represented. In the Mosaic peace-offering the right shoulder was offered before the altar and retained by the priest, and this ritual was also observed by the Babylonians.

Of objects with foreign connexions from the Temple deposits, I should mention the 'lion hunt' scarab of Amenhetep III, who reigned between 1411 and 1375 B.C. Duplicates have been found in many provincial centres, and they record that the king killed "lions terrible, 102, by the 10th year of his reign". It was found on the altar of Structure III, but in common with the ivories and glass associated with it, these temple treasures seem to have been preserved since the enlargement of Structure I. Its presence at Duweir marks the point of junction with Egyptian written records and opens their rich annals of imperial expansion.

A Mykenæan cup (1500–1400 B.C., according to Helladic sources) is the first link with that culture, and it formed part of the altar-group belonging to Structure I. Some twenty-five forms are identical with the wares usually attributed to Cyprus and Syria.

The development of the temple can be traced through two hundred and fifty years of comparative peace and growing prosperity. The earliest structure was founded about 1475, and the third building, greatly enlarged, was destroyed by fire with most of the temple equipment about 1223 B.C., on evidence provided by a cartouche of Rameses II. This destruction also overwhelmed the Bronze Age town; indeed, most of the contemporary cities of Palestine and Syria were involved in a similar catastrophe.

There is nothing to show from Duweir as to the force which effected the destruction. It was only gradually that the life of the city was resumed, and it is likely that foreign trade connexions were not so flourishing as they had been in the late Bronze Age town, when examples of threē scripts, Sinaitic, hieroglyphic, with its cursive form hieratic, were in contemporary use, quite apart from cuneiform which also occurs in south Palestine.

From the beginning of the Iron Age other sources of written record become helpful. The Old Testament is full of administrative detail, and it is clear that the officials of the time were occupied in problems of local defence, particularly after Solomon's death about 935 B.C. Rehoboam, his son, fortified fifteen cities in Judah, and Lachish, with its neighbour Azekah, among them.

An inner and outer stone wall still encircles the mound at Tell ed Duweir. Though it is battered and burned, the line can be traced without a break. The upper courses were built of brick, and both brick and stone surfaces were faced with a coat of white lime plaster. Though this system of defence may have been intended as protection against Egypt, there is good reason to attribute the signs of the first attack to the invasion of the Assyrians under Sennacherib about 700 B.C. The commemorative relief in his palace at Nineveh, found by Sir Henry Layard, shows the assembled might of his army before the city of Lakhisha. The method of attack is shown in great detail, and at Tell ed Duweir we see corroborative evidence of some similar event; we find sling shots, fragments of scale armour, a helmet crest and arrowheads in profusion.

A cave had been used about this time as a repository for skulls; they had been thrown in through a hole in the roof and many had rolled down the conical heap to the sides of the chamber. The bodies had been moved to this cave after disintegration, and a few skulls showed signs of burning. The series of seven hundred skulls has been studied by Mr. D. L. Risdon with Dr. G. Morant of the Galton Laboratory. The adults were younger on the average than the usual cemetery population, which gives colour to the supposition that they died in a catastrophe. Mr. Risdon's statistics place the Lachish series in close connexion with the contemporary Egyptians, with two differences.

Sir Arthur Keith, in a valuable article published in the Palestine Exploration Fund Quarterly Statement (January 1940), wrote as follows: "Mr. Risdon notes among the Lachish people two characters which are non-Egyptian, namely narrowness and prominence of the bridge of the nose and curvature of the cheek-bones. From these characters alone I should have suspected that the Lachish people were

racially different from the Egyptians." Sir Arthur referred to the Lachish series as "the first complete account of the racial characters of a people living in Palestine during biblical times".

In the same depository of skulls, three examples were found to be trephined. This operation was common so early as neolithic times in Europe, North Africa and even the two Americas. It is also practised by primitive people to-day. The specimens from Duweir are unique, being the only ones so far discovered in the Near East, and their presence shows once again the many influences which affected the coastal strip. It is not possible to say whether the operation was therapeutic or magical. Two methods occur at Duweir: one was removal of the disk by cross cuts, as seen in two skulls where the sharp edges indicated that the patient died shortly afterwards, and there is a triangular type more akin to the European method of scraping, which gave the patient a better chance of recovery.

The Babylonian campaigns which mark the virtual end of the city are well attested both in their own and Biblical records. The period between 700 and 600 B.C. is represented on the mound by a district of shops and houses protected by a city wall which had been repaired since Sennacherib's attack. The Babylonian commander was aware of the perils of leaving partially destroyed fortifications, and he burned long sections of the wall by heaping great piles of olive trees and brushwood against them. In the charred debris, we still find the calcined olive stones which show that destruction took place in the autumn just before harvest time.

At the gate of the city, in the guard-room of this last period of fortification, while sorting a mass of blackened sherds, Mr. Starkey with Mr. Harding found the now famous "Lachish Letters". They form an invaluable link with the Bible record; for the first time we can study the handwriting of contemporaries of the prophet Jeremiah, written in the beautiful pre-exilic script, which is allied to our own alphabet through the Phœnicians. Dr. H. Torczyner, who undertook the publication of the letters, has noted many Biblical names and directs attention to phrases which have all the flavour of Old Testament language. Letter IV includes the sentence, "if in his turning (on his rounds) he had inspected, he would know, that for the signal stations of Lachish we are watching, according to all the signs which my Lord gives, because we do not see (the signals of) Azekah". These words imply that Lachish and Azekah were still linked in the same system of defence as in King Rehoboam's reign.

The defences of Duweir were finally broken about 600 B.C., but the town enjoyed a short period of revival during the Persian occupation. The Persian residency crowned the site for a few years, and was built on the massive foundations of the earlier Judæan fort.

In presenting the shadowy traces of the many peoples who passed by, it is hoped that in years to come some one will carry forward the work which James Leslie Starkey began.

MUSCULAR AND MENTAL RELAXATION IN PEACE AND WAR*

By Dr. E. J. BOOME

RELAXATION means more than just a holiday or a lazy time; it means concentration and not inertia.

The relaxation of muscular exercises, in moderation, re-creates the body and conduces to physical fitness, which is one of the chief bases of mental poise and well-being. But relaxation is much more far-reaching in its effects and more constructive in its processes. Beginning with a muscular loosening, it leads to a gradual re-creating of the individual. This form of self-treatment, apparently very simple, is more complex than is realized by the beginner.

Everyone feels the state of tension in the world to-day and the need for some antidote to counteract it. This tension—always in the world even in time of peace—is greatly aggravated by war conditions. In individuals it is expressed by muscular hypertonicity, in mental worry, fear, anxiety, in emotional repression and nervous strain. These factors sometimes react upon each other and cause a breakdown.

Nervous cases tend to become more frequent in days of fear and anxiety such as we have all been through during the past four years. Some people come back automatically to normal, but others do not. Often the attitude of friends and relations intensifies the feelings of these people. Even medical men sometimes say: "There is nothing wrong with you, it's only your nerves or your imagination". Nowadays, we are more careful because we realize that such an attitude only makes these patients ponder more over their ailments, imaginary or otherwise. This makes matters worse, as they become almost convinced that there is really something wrong with them and turn to patent medicines which claim to cure all their ills.

Annie Payson Call, in her book "Power Through Repose", very wisely said:

"Where is the good of taking medicines to give us new strength, while at the same time we are steadily disobeying the laws from the observance of which alone the strength can come ? No medicine can work a man's body, while the man's habits are constantly counteracting it. Where is the use of all the quietening medicines if we only quiet our nerves in order that we may continue to misuse them without their crying out ? They will cry out sooner or later."

In order to prevent this, we must first investigate the causes of hypertension.

The body reacts on the mind and vice versa. This happens in cases of real illness, particularly if the patient has never been ill before. He gets anxious about his condition and even becomes angry with himself for being ill. This sets up and increases mental and muscular tension and retards recovery. A cheerful patient, on the contrary, generally recovers more quickly.

Work never killed anybody, but the *worry* which is added to and mistaken for work has caused many a breakdown. In war-time there is often the element of fear added, which increases the wear and tear of one's daily occupations. Many people waste 50 per

* Substance of a Chadwick Trust Lecture delivered on October 5 at the Royal Institute of Public Health and Hygiene.

cent of their efficiency and adversely affect the environment of those working under them because of their own anxious temperaments. Often they cannot see the harm they are doing to themselves and others and scornfully refuse any suggestion of treatment.

In Great Britain 20,000,000 are employed, many on war work. 40,000,000 weeks a year are lost from sickness, of which it is estimated that we lose 8,000,000 weeks of work a year through gastric and nervous disorders. Many so-called gastric disorders are not due to disease of the gastro-intestinal tract but to functional dyspepsia—an emotional disturbance which shows itself by gastric disturbances. A similar proportion of imagined 'nervous dyspepsia' found among civil defence workers (ambulance, fire brigade and rescue services) clear up with a change of scene and rest.

War-time restrictions which control the lives of 8,000,000 civilians give a sense of frustration, and may cause nervous illness and anxiety in some people. This discontent and frustration caused by war-time conditions may be alleviated by the Ministry of Labour schemes for 'rest-break' homes for war workers. These are to be greatly extended, and soon a network of these hostels will be established throughout Great Britain. Pamphlets such as "Fighting Fit in the Factory", explaining the necessity for rest whenever possible and telling workers the best way to relax, can help.

Much is being done by the Ministry of Labour and National Service to make the life of the workers as harmonious as possible.

Some so-called 'authorities' say that complete relaxation is impracticable in everyday life. It is not only practicable but also desirable. The complete process is obviously not possible in all circumstances and places, but we need not use so much unnecessary muscular energy in the ordinary ways of life, such as clenching the jaw when writing or pushing against the floor with the feet when riding in a bus. Legs should sometimes go 'off duty'.

Relaxation in Crafts and Sports

Most crafts and sports depend upon rhythm to attain the best results. Rhythm again depends on correct timing, which can only be carried out by muscular balance. This is brought about by alternate muscular contraction and relaxation. The excitement of some forms of sport may cause hypertension, and the more this increases the less efficiently are the necessary movements carried out.

In yachting the helmsman must have complete muscular control to steer a steady course, as well as being mentally wide awake to take decisions and give orders to his crew.

Rhythmic timing is shown in such diverse sports as boxing and fishing, while success at golf and many other sports depends on accurate timing.

Eric Linklater in the "White Man's Saga" gives a beautiful description of the boxer. He says:

"There is beauty in boxing when men stand upright and step lightly. There is design in their movements, and significance as charged as that of the ballet. Counterpoise follows on poise, defence on attack, reaction on action with a balance, a trim symmetry that quickens as the blood beats and grows and swells into a pounding orchestration of thudding fists and shifting, sliding feet; for an instant there is repose, the sculptured austerity of two figures, motionless, poised like statues on the verge of life; and then their static energy is again released to mingle dynamically in a crescendo of action".

Tobias Matthay in "The Visible and Invisible in Piano Technique" emphasizes the important changes of state of exertion and relaxation of the playing limb which form the real basis of good technique, but which, being invisible, have escaped attention.

Physiological Facts with Regard to this Thesis

Resting muscle is alkaline, whereas over-worked or fatigued muscle contains lactic acid. The amount of the latter is in proportion to the amount of tension.

Pain and violent emotion of any kind such as anger or fear cause chemical changes by releasing toxic substances and excessive glandular products into the system, which have to be carried away and thrown out by the blood stream into the channels of excretion. Excessive adrenalin in the blood may lead to vascular troubles and other harmful conditions unless dissipated either by action or muscular relaxation.

Long-distance runners are massaged so that the muscle gets rid of its waste products more quickly. Return flow of blood to the part is increased after contraction and relaxation, so circulation is increased.

Medical Examination

Muscular relaxation is of the greatest assistance in medical examination. If a candidate for superannuation and pension or life insurance presents himself before the medical examiner strung up to a state of tension, he will show signs of quickened heartbeat and his chest will tighten up with inhibition of breathing. He may stand stiffly to attention, thinking he is thus making the best of himself, which causes his blood pressure to go up under the strain he makes himself undergo. If the medical man can persuade him to relax the task is much simpler, time is saved and the candidate feels happier. A 'bedside manner' really is a useful, if not an essential, asset to a medical man. It means he is himself relaxed, has poise and can thus command confidence.

Often the practice of relaxation can cure stammering and relieve high blood pressure.

Stammering

This distressing condition was one of the reasons I became interested in relaxation. In 1919, I was placed in charge of centres for stammerers. In those days we used only voice training and speech drill, treating the symptom and not the cause, and the results were depressing.

Psychological and temperamental readjustments are of great importance in the treatment because the stammerer's outlook on life in general and himself in particular is depressed and usually negative.

Relaxation calms and reassures the sufferer and enables him to carry out his day's work quietly and efficiently. All his characteristic symptoms of tension disappear and he becomes a strengthened, stable and self-respecting person, ready to face the world with confidence.

Asthma is a nervous complaint rather like stammering. Good results are obtained by relaxation therapy in these cases, and diminution in frequency and severity of attacks follows treatment. The nervous tension and anxiety so frequently found in these cases are much diminished. The breathing becomes easier, confidence is restored and the distress is abated.

With regard to birth palsy, I have seen excellent results with muscular relaxation for the paralysed limbs. Relaxation seems to give increased confidence, with consequent improvement in gait, and also to make the best use of the injured muscle.

In cases of tennis leg and tennis elbow, relaxation is an important part of the treatment.

According to the late W. Trethowan, 85 per cent of cases of spinal curvature are due to functional nervous disorder and are not indicative of any organic disease. This condition usually denotes that a larger call is being made on the child than its general physique will stand. It is often found during adolescence and may be associated with enlarged tonsils, adenoids, constipation or over-pressure in study.

Attention to the general health usually results in the disappearance of the defect. Early cases of spinal curvature respond better to a midday rest in the recumbent position than to exercises. It is useless to try to heal the muscles by working them. Muscular relaxation practised under expert guidance is of untold value ; it not only rests the patient but also is definitely curative in effect.

An elementary school teacher of great experience told me that children suffered less when the *Blitz* was at its height, because they were in the shelters early and went to sleep. During later raids they no longer went to the shelters regularly but played in the streets and went to bed late. When the sirens sounded they were got out of bed, with resulting greater fatigue and emotional disturbance. In one day raid in 1943 there were bombs and machine-gunning in the streets which caused an increased amount of tension at the time and delayed progress in relaxation therapy at some of our speech centres. On the morning after the winter raids of 1943 it was interesting to notice that the children relaxed voluntarily for a much longer time than usual.

The evacuation of school-children has shown that far more children suffer from enuresis than was generally supposed. Some cases are the result of neglect in training, but the majority are attributable to nervous causes. Some children develop this habit on being evacuated to the country, but in many cases it stops if the child settles down happily. If the enuresis is of long standing and the child is unhappy, it may be necessary for the case to be sent to a special hostel, though it is doubtful whether this segregation is satisfactory in all cases. A nervous, sensitive child may develop a sense of shame difficult to eradicate even after the enuresis has been cured.

Stammerers suffering from enuresis have been cured of this habit through relaxation, and cases have been known where the enuresis has ceased after one week's attendance at a centre.

In the case of writer's cramp, there is, in addition to the physical condition, a psychological factor. These cases are helped greatly by relaxation.

Dr. Grantly Dick Read says that pain in child-birth could be largely eliminated if mothers were trained to relax from the fourth to fifth month of pregnancy for a few minutes each day. So much pain in normal child-birth is due to a misapplication of the sense messages of fear to the brain, which leads to a tension of the fibres.

Conclusion

Relaxation in some form has been known throughout the ages. Even animals and plants relax for specific periods.

Primitive races still instinctively use it, and ancient races of the East have never ceased to practise it, perhaps because their civilization is of longer duration than ours and was arrived at more slowly.

There is nothing new in the art of relaxation, and its complete story has yet to be told. It is not the panacea for all ills, but it can alleviate physical, nervous and emotional conditions.

The inner peace and tranquillity that may be developed by means of relaxation may pervade a man's life ; so that we can still say with the Psalmist : "Commune with your own heart upon your bed, and be still".

SYNTHESIS OF NEW SPECIES OF WHEATS*

By Dr. ANTON ZHEBRAK

Timiryasev Agricultural Academy, U.S.S.R.

As generally known, the species of wheats existing in natural conditions are classified into three chromosome groups of 14, 28, and 42, according to the number of chromosomes in their somatic cells. The most widespread species represented by a great number of varieties of races, biotypes and agricultural sorts is the bread wheat *Triticum vulgare*. This species is the most polymorphic and is represented by spring as well as winter sorts of wheats. The record frost-resisting agricultural sorts are found only among *Triticum vulgare*, which belongs to the group with the highest number of chromosomes.

The fact that a number of very valuable agricultural and biotypical qualities has developed in the process of evolution among the highest chromosome species of wheats *T. vulgare*, supports the chromosome that the high chromosome species are undergoing evolution and adapting themselves to various conditions of environment more rapidly than the species with a low number of chromosomes. Hence the problem of introducing wheats into new areas might best be solved by increasing the number of chromosomes. The above, as well as a number of purely theoretical considerations, led us to take up the question of obtaining high chromosome forms of such an important cereal as wheat. However, as most species of wheats are already polyploids, no more valuable and more fertile types can be obtained by an increase in the number of chromosomes in pure wheats, as this would probably lead to highly sterile forms.

We therefore began our effort to obtain high chromosome forms of wheats by doubling the number of chromosomes of interspecific hybrids and not that of pure species.

We selected two species of wheats for hybridization, namely, *Tr. monococcum* and *Tr. Timopheevi*. Both these species are immune from a number of fungal parasites and insects and, what is most important, they have isolated chromosome complexes producing, when crossed with other species, absolutely or highly sterile hybrids. By increasing the number of chromosomes of such highly sterile hybrids we restore fertility and obtain amphidiploid types with higher numbers of chromosomes than those of the parental species of wheats.

* A report on this work was made by Dr. Anton R. Zhebrak in 1940 at the December session of the Timiryasev Agricultural Academy, in 1942 at the November session of the Academy of Science of the U.S.S.R. in Tashkent, and was repeated at the s ssion of the Timiryasev Academy in March 1943.

We began our research into methods of obtaining amphidiploids of wheats in 1936. At first, in order to increase the number of chromosomes, we used various agents—chemicals, temperature, X-ray treatment, etc.—which had been employed by numerous scientific workers prior to us. Unfortunately these agents did not lead to the desired results. Only in 1938, after the publication of the work of Blakeslee and Avery on obtaining polyploid forms among plants by colchicine treatment, did we succeed in obtaining the first amphidiploid types of wheat. At that time we had obtained hybrid seeds of the following combinations: *T. durum* Desf. × *T. monococcum* L., *T. polonicum* L. × *T. durum* Desf., *T. durum* Desf. × *T. Timopheevi* Zhuk., *T. persicum* Vav. × *T. Timopheevi* Zhuk.

In the spring of 1938 we treated hybrid seeds of the above-mentioned combinations with a 0·1 per cent colchicine solution and obtained amphidiploid spikes from the following hybrids: *T. durum* Desf. × *T. monococcum* L., *T. durum* Desf. × *T. Timopheevi* Zhuk., *T. polonicum* L. × *T. durum* Desf.

The amphidiploid spikes *T. durum* × *T. monococcum* and *T. durum* × *T. Timopheevi* were of normal fertility and widely differed from the sterile amphihaploid spikes. We found forty-two chromosomes in the somatic cells of the amphidiploids *T. durum* × *T. monococcum* and fifty-six chromosomes in the amphidiploid *T. durum* × *T. Timopheevi*.

The spikes of *T. polonicum* × *T. durum* hybrids which had been subjected to treatment with colchicine solution in the seed stage contained various numbers of grains: 7–10 and 25–30. Next year (1939) the plants obtained from ears of various fertility were investigated. It was discovered that the ears with low fertility contained amphidiploid grains giving 56-chromosome plants, while spikes with a high fertility gave plants with twenty-eight chromosomes. Thus on the basis of these investigations we ascertained that in the highly sterile *T. durum* × *T. monococcum* and *T. durum* × *T. Timopheevi* hybrids the doubling of the number of chromosomes led to the restoration of normal fertility while the increase of the number of chromosomes of normally fertile hybrids of the first generation of *T. polonicum* × *T. durum* produced polyploid plants of low fertility. We are continuing experiments with them, however.

The amphidiploids *T. durum* × *T. monococcum* have forty-two chromosomes in their somatic cells and occupy an intermediate position between *T. durum* and *T. monococcum*. We consider this amphidiploid a new species of wheat and have named it *Triticum Edwardi* Zheb. The characteristic peculiarities of this species are the intense greenness of the sprouts and the adult plant, the erectness of the stems and their high tillering, the lack of pubescence (hairlessness) of its glumes. The glumes are triangular with blunt crenature. Spikelets are arranged along the stem in a straight line. The side of the ear is wider than the front. The kernel is large and somewhat asymmetrical.

We have classified the amphidiploid *T. durum* × *T. Timopheevi* (2n=56) as new species, *Triticum soveticum* Zheb. In 1939–40 we obtained such 56-chromosome types by crossing *T. Timopheevi* with numerous sorts of nineteen varieties of *T. durum*, six varieties of *T. turgidum*, three varieties of *T. persicum*, three varieties of *T. polonicum* and one variety of *T. orientale*.

Thus 56-chromosome amphidiploid types have been obtained from crossing *T. Timopheevi* with thirty-two varieties belonging to five 28-chromosome species. As there is no great difference in external morphological characteristics and all the above-mentioned amphidiploid types may be easily crossed among themselves and contain the same number of chromosomes, we have classified them as a single botanical species *T. soveticum* Zheb. The amphidiploids of different varieties of *T. durum* × *T. Timopheevi* will form the respective varieties of the new species *T. soveticum* ssp. *durum* Zheb., and similarly for other crosses. Thus the species *T. soveticum* Zheb. obtained experimentally is represented by five sub-species and thirty-two varieties. The number of varieties can be increased by mutational changes, as well as by taking advantage of the variability of the hybrid by crossing different sub-species of *T. soveticum* between themselves. We effected such crossing in 1942.

The most characteristic and general attributes of all sub-species of *Triticum soveticum* Zheb. are the following: dark green pubescent shoots, erect bush and dark green colour of the stem and entire plant. The leaves are pubescent. At the base of the leaf the plant has a ligule and auricle. It possesses high tillering capacity. The spike stem does not break easily. The glumes of the spikelets are pubescent. The colouring of the spikes varies: white, red, black and intermediate shades. The grain is red, glassy, large and long—8–12 mm. The absolute weight of a thousand grains is about 100 grams. This species varies widely in all combinations. It has 56 chromosomes.

The amphidiploids of *T. Timopheevi* with different species of 28-chromosome wheats occupy the intermediate position between *T. Timopheevi* and these species. But as they differ widely from the original species in many characteristics, their number of chromosomes and their ability to cross, we place them in the new species, *T. soveticum*, but in designating the sub-species retain the name of the original 28-chromosome species with which the crossing with *T. Timopheevi* was performed. The peculiarities of the varieties of the 28-chromosome wheats in *T. soveticum* are not always apparent owing to the prevalence of a number of morphological characteristics of *T. Timopheevi*.

The new properties of the amphidiploid types of wheats are: (1) the exceedingly large absolute weight of the kernel, which greatly exceeds that of the parent species (1,000 selected kernels of various combinations weigh between 100 and 110 gm.; the weight of a thousand average grains is about 80 gm.); (2) the amphidiploid species have a longer vegetative period than their parents; (3) various amphidiploid combinations such as sub-species *durum*, *turgidum*, *orientale* have acquired the ability to survive the winter in Moscow.

A new type as regards the number of their chromosomes are the amphidiploids *T. vulgare* × *T. Timopheevi* and reciprocal crossings. Such amphidiploids are obtained from the following varieties of *T. vulgare*: *lutescens*, *milturum graecum*, *alborubrum*, *albidum* and *erythrospermum*. These varieties include spring as well as winter forms. The amphidiploids resulting from crossing with the winter sorts of *T. vulgare* are spring wheats with late ripening. The fertility of these amphidiploids is not high, usually one or two kernels per spikelet. They have seventy chromosomes and belong to the decaploid group. The amphidiploids vary greatly in their morphological characteristics and the length of their vegeta-

tive period. We have classified them as a separate species called *Triticum Borisovi* Zheb. The basic peculiarities of this type are the dark green colour of the shoots, the pubescence of the shoots and leaves and the glumes of the spikelets. The stem of the spike is only slightly brittle. The grains are tightly wrapped into flower paleæ. The number of chromosomes is seventy.

We have also obtained 70-chromosome amphidiploids from crossing *T. durum* × *T. vulgare*. Their fertility is not high but they differ in their morphological characteristics. In some combinations the kernel is good. A more complete account of these amphidiploids will follow later upon completion of more extensive research.

Both the 70-chromosome amphidiploid types have a common peculiarity: their lower fertility as compared with the 42- and 56-chromosome types.

In conclusion, I wish again to stress that colchicine is exceedingly effective as a factor in increasing the number of chromosomes. This is shown by the facts outlined in our work, from which it may be seen that, in a brief period, we succeeded in obtaining more than ninety amphidiploid types of wheat belonging to the three chromosome groups 42, 56 and 70, which may be considered as new botanical species. To the best of our knowledge these amphidiploid types of wheat have been obtained for the first time, and amphidiploids in general, in such large quantities, also for the first time.

OBITUARIES

Dr. J. K. Roberts, F.R.S.

It is difficult for the colleagues and friends in the Laboratory of Colloid Science, and others who have been intimately connected with John Keith Roberts, to realize that he has departed from us. He died on April 25, aged forty-seven.

I first met 'J. K.' when he was working in the Cavendish Laboratory. At that time, under the genial guidance of Lord Rutherford, the main interest in the Cavendish lay in the problems of nuclear structure. To 'J. K.', however, the nucleus had no attraction; he was both by training and inclination steeped in the classical tradition of physics based upon thermodynamics. He was at the time engaged upon the problem of the extent to which thermal energy is exchanged when gas molecules hit and leave a solid surface. He found that the values for the accommodation coefficient were coming out unexpectedly higher than anticipated from Baule's calculations. In my Department we were searching for different methods by which layers of gas adsorbed at metal surfaces could be detected and examined, and it seemed possible that the high values for the accommodation coefficient which Roberts found were due to the presence of a chemisorbed layer of gas on the tungsten wire which he was using. If this proved to be the case, the accommodation coefficient might serve as a useful tool for exploring surfaces.

Roberts welcomed with enthusiasm the suggestion of moving from the Cavendish to next door, and taking up this field of inquiry. He devoted the next ten years of his life to this problem. In this investigation he was strikingly successful. Roberts not only showed how one could trace and follow the building up of adsorbed monolayers on tungsten wires by means of the accommodation coefficient of neon as an indicator, but also later developed methods for actually measuring the heat of adsorption of gases on thin wires by making the wire one arm of a Wheatstone bridge. A series of papers both experimental and theoretical testify to the great skill, painstaking accuracy, and attention to detail which characterized all his work. Methods had to be worked out for circulating pure neon over scrupulously clean wires and for the admission of gases at minute but regulated pressures. The apparatus was essentially simple, but the elimination of contamination in the system indicates the extraordinary cleanliness which he achieved. Many important discoveries were made, and what had hitherto been matters of opinion experimentally tested. Thus it was found that when the tungsten wire was clean, chemisorption of several elementary gases occurred without appreciable energies of activation, that a slow process of activated diffusion could take place into the wire, and that gases could be quantitatively displaced from the surface. When diatomic gases were chemisorbed as atoms, holes were left in the surface which play an important part when chemical reactions take place in the adsorbed phase. He showed that there could be a transition from immobile to mobile monolayers, and revealed how the influence of mutual interaction between the adsorbed particles could be traced both in the form of the adsorption isotherm and in the thermal behaviour on adsorption.

Apart from this field of inquiry, which he made particularly his own, Roberts took a great interest in many other problems, especially in the mechanism of melting of a crystalline solid and in the origin of the elasticity in rubber. He was always ready to give his advice and criticism to those commencing research. Here, for Roberts, no trouble was too great, no time too long. Many have gained from the lasting impression he made by his directness and simplicity of approach in experimental attack, his insistence upon rigour in argument and soundness in thermodynamic treatment. His lectures were clear and attractive, and his book on thermodynamics has already gone into the third edition. Little can be said at present about his activities in the War, but he took a post in a naval research establishment that was difficult administratively, and involved research and development along important and novel lines. Here he was an unqualified success.

In the laboratory Roberts was always cheerful and ready to deal with all the vexatious details which arise—this in spite of his health, which was never good. At times a leg gave him much trouble, but no one ever heard a word of complaint. He took much pleasure in the fact that his work was appreciated, both at home and abroad. He had been elected to the fellowship of the Royal Society and quite recently made a fellow of Christ's College, and was looking forward to his return to Cambridge, where his heart lay.

Eric K. Rideal.

We regret to announce the following deaths:

Dr. J. A. Campbell, of the research staff of the National Institute of Medical Research, on April 20, aged sixty.

Lieut.-Colonel Stanley Casson, reader in classical archæology in the University of Oxford, aged fifty-four.

Mr. H. B. Walters, O.B.E., keeper of Greek and Roman antiquities in the British Museum during 1925–32, on April 24, aged seventy-seven.

NEWS and VIEWS

Botany in the University of London

King's College

PROF. T. A. BENNET-CLARK, of University College, Nottingham, has been appointed to the University of London chair of botany, tenable at King's College, London, as from October 1944. Prof. Bennet-Clark was educated at Marlborough College and Trinity College, Cambridge, and in 1923 was placed in the first class of the Natural Sciences Tripos (Part II) list and was the Frank Smart Prizeman. He worked for a time under Dr. F. F. Blackman until, in 1924, he was appointed as assistant to the professor of botany, Trinity College, Dublin. During these years, research on the metabolism (especially the respiration) of succulent plants yielded results of great interest. This line of research continued after his appointment in 1931 as lecturer in botany in the Victoria University of Manchester. His appointment to Manchester coincided with an increase in the number of research students there, and a large proportion were then attached to plant physiology and under his guidance investigated the metabolism, especially of acid-producing plants, including fungi, while research on another aspect of plant physiology served to focus attention on the important part which protoplasmic activity may play in water absorption by plant cells. Under his direction plant physiology at Manchester received a considerable stimulus. In 1936 he was appointed to the chair of botany at University College, Nottingham, where a heavy burden of teaching has not restricted his other activities. Since 1937 he has served the Society of Experimental Biology as botanical secretary. Botanists throughout the country will wish him success and happiness in his new appointment.

Birkbeck College

BY the appointment of Dr. C. T. Ingold to the chair of botany, Birkbeck College maintains a strong mycological tradition built up during the period of office of Dame Helen Gwynne-Vaughan. Dr. Ingold is well known for his studies on the aquatic Hyphomycetes, and for work on mechanisms of spore dispersal in fungi. He is a keen and first-class naturalist, and one of the limited band of those who 'know their higher Basidiomycetes', so that it is a real pleasure to tramp the country with him as guide. He conveys his enthusiasm with success to students and colleagues. Dr. Ingold was a student of the Queen's University, Belfast, and has served on the staff of the University of Reading. Latterly he has been head of the Department of Botany at University College, Leicester. His published work includes papers on permeability, aquatic fungi and algæ, and an attractive book on spore dispersal.

Transmutation of Wood

IN a short message printed in *The Times* of April 17, attention is directed to what is claimed to be a new chemical treatment which makes wood nearly as hard as steel, transmuting it into a new material, part wood and part plastic, announced by the du Pont Company in the United States. From the brief description given, it appears that this new material is only one of the many forms of what has become known as 'improved wood'. Until specimens have been examined it is not possible to verify the claims. In preparing a material of this kind it is, in general, sought to improve the strength properties and the dimensional stability of wood by a combination of impregnation with synthetic resins and densification under heat and pressure. The manner of effecting this varies from process to process. It was believed for some years that the use of synthetic resins was essential for the production of improved wood, but only recently the U.S. Forest Products Laboratory has demonstrated that much of what is done by the earlier processes can be achieved through the use of heat and pressure alone.

In the use of synthetic resins for making 'improved wood', most success has been achieved with the phenol-formaldehyde type. Hitherto the amino resins have not been favoured for the manufacture of improved wood, presumably because they have been found to be chemically not so stable as some other types and to have somewhat inferior ageing characteristics under warm and humid weather conditions. It remains to be seen, therefore, whether the urea/formaldehyde resin involved in the Dupont process incorporates any new feature which marks it out as superior to others of its class. It is stated that the monomer combines with the natural acids in the wood; but the more conventional view of the setting process would appear to be that these acids merely behave like all other acids which are known to catalyse the setting reactions in urea/formaldehyde resins. The two claims which it will be most interesting to confirm are that almost any species of timber can be treated—particularly as nothing is said as to the thickness of piece which can be treated—and that all dimensional change is prevented. So far as existing experience goes, this latter claim seems to be incompatible with the implied retention of the best other properties of wood. Should these claims hold good after a period of years, the process will mark a big advance in the field of wood-plastic composites.

Development of the Highlands of Scotland

A CRITICAL study in the February number of *Agenda* by Mr. Hugh Quigley on "The Highlands of Scotland: Proposals for Development", urges that the one policy which will make a permanent contribution to the Highland civilization is in effect to make a collective regional unit of the Highlands after the pattern of the Tennessee Valley Authority. Mr. Quigley strongly criticizes the creation of the North of Scotland Hydro-Electric Board, which has only indirect influence on the problem of Highland reconstruction; it regularizes the supply of electricity, but electricity has not been, and is not, the sole essential for new developments. The lack of industrial enterprise is not to be attributed to any defect in availability or price of electricity. The economic condition of the Highlands has not changed materially since the Hilliary Committee reported in 1938. The War, if anything, has caused further deterioration through cutting of timber, much of it immature, and restriction of communications, but has, on the other hand, brought greater activity to the ports. Reconstruction cannot be carried out piecemeal but must cover as wide a range of economic factors as the state of our knowledge and the limits of administrative ability will permit.

Reconstruction in the Highlands should be entrusted to a Highland planning authority with powers similar to those of the Tennessee Valley Authority and over-riding control over the North of Scotland

Hydro-Electric Board. The activities of the Forestry Commission should be wound up so far as they apply to the Highlands of Scotland, and its functions transferred to a Scottish national parks section of the planning authority. The Scottish Department of Agriculture should cease to own and administer land and its holdings transferred to the planning authority. The Planning Section of the Scottish Department of Health should be considerably extended and its functions widened to cover supervision of development schemes proposed by the planning authority, and, until the latter is formed, of the North of Scotland Hydro-Electric Board. Reform and re-alignment of Highland local authorities must accompany or result from the creation of a planning authority: in their present form they are incapable of contributing usefully to any fundamental scheme of economic reconstruction.

Patent Law Reform

A COMMITTEE has been appointed to consider and report whether any, and if so what, changes are desirable in the Patents and Designs Acts, and in the practice of the Patent Office and the Courts in relation to matters arising therefrom. In particular, the committee is to consider the conduct of legal proceedings arising out of the Patents and Designs Acts, including the constitution of the appropriate tribunals; and, in connexion with the prevention of the abuse of monopoly rights, it will suggest amendments to facilitate settlement and the reduction of the cost of legal proceedings and encourage the use of inventions and the progress of industry and trade.

The committee is constituted as follows: Mr. Kenneth Swan, K.C. (*chairman*), Mr. Hubert Gill, Mr. James Mould, Captain B. H. Peter, Dr. D. R. Pye, Mrs. Joan Robinson, Mr. H. L. Saunders and Dr. A. J. V. Underwood.

Trade Unions in Great Britain

MRS. MARY AGNES HAMILTON's pamphlet "British Trade Unions" (Oxford Pamphlets on Home Affairs, No. H.47. Oxford University Press. 6*d*. net), which gives a brief survey of trade union history in Britain, is of particular interest for its description of the position of the trade unions in relation to the State and to society in Britain to-day. While the value of the trade union as a training ground for democracy is well brought out, and also its dependence upon democracy as a condition of effective functioning, neither the essential strength ncr the weakness of trade unionism is indicated so clearly as might be expected. Mrs. Hamilton quotes Mr. Bevin's enunciation of the central idea "the liberty of the ordinary man and the right relationship between fellowmen" which is also the central idea of democracy; but she fails to point out that the co-operation and collective bargaining represented by the trade unions is indispensable in the industrial and economic conditions of to-day. Without them our war effort could not easily have attained its present pitch, nor could many advances in welfare and the like have been so readily achieved. Equally she overlooks the innate conservatism of the trade unions, which is the real weakness that has hindered their making their full contribution to the development of democratic ideas and practice and to social and economic progress—a weakness as marked in the newer unions of technical and professional workers as among the older unions of manual workers in its customary sense.

Institute of Metals

IN his presidential address to the Institute of Metals on March 15, the new president, Dr. W. T. Griffiths, devoted much of his attention to the widefelt need for a greatly increased number of trained metallurgists in industry. Apart from stressing the demands to be made on institutions of university standing, he mentioned the probability that, in conjunction with other metallurgical bodies and the Board of Education, there is the probability of the immediate institution of National Certificates in Metallurgy similar to those already existing for engineering. This movement received both his own welcome and that of the Council of the Institute. The demand for the greater recognition of the profession of the metallurgist is under consideration by all three metallurgical institutions, and the probability was mentioned that some qualifying board, independent of, but working in co-operation with those bodies, would soon be set up. The desirability of co-operation between the Institute of Metals and the Iron and Steel Institute, already close, becoming still more intimate, a development to be welcomed on many grounds, was stressed, and the announcement that Mr. Headlam-Morley, the secretary of the Iron and Steel Institute, is to act, for the time being, as secretary of the Institute of Metals in succession to Mr. Shaw-Scott, is a clear indication of such an increasing unity of purpose.

The Institute of Metals Medal for 1944 was awarded to Lieut.-Colonel the Hon. R. M. Preston, president during 1940–42 of the Institute.

The Golgi Apparatus

IN his presidential address to the Section of Zoology and Entomology of the thirty-first Indian Science Congress at Delhi, Prof. Vishwa Nath gave a general account of his own views on the nature of the Golgi element. He regards Golgi nets, dictyosomes, batonettes, rods and crescents as optical illusions, and one appearance only as genuine—that of a spherical osmiophil and argentophil cortex enclosing a spherical chromophobe core. These plainly correspond with the externum and internum of Hirsch, and although Prof. Nath is strongly opposed to the vacuome theory of Parat, yet it seems likely that the chromophobe cores correspond with Parat's vacuoles. He opposes strongly the opinion that the Golgi element is concerned with cellular secretion, and argues that, on the contrary, it is transformed into such objects as others think it secretes. He is concerned to show that in forming the acrosome, the Golgi element is completely used up, a conclusion with which many students of this cell inclusion will find themselves in disagreement. It seems possible that the difference between secretion and transformation may to some extent be a verbal one, scarcely calling for the expression of such strong opinions as those of Prof. Nath. The greater part of the address was very clearly worded. Students of the Golgi element find themselves in disagreement on several matters, and it is helpful to all concerned when views are unequivocally expressed.

Nutrition Problems in Venezuela

THE August issue of the *Boletín de la Oficina Sanitaria Panamericana* contains a note on this subject, which was discussed at the eleventh Panamerican Sanitary Congress at Rio de Janeiro in

1942. As regards nutrition in Venezuela, the same conditions exist as in the other Caribbean Republics, and in some respects as in those in the other Latin American republics. All the publications on the subject come to the same conclusion, namely, that the labouring class is inadequately fed and consumes excessive amounts of carbohydrates compared with other elements such as proteins, vitamins, etc. In many cases a family has to spend 75 per cent of its income on food alone. Farm workers, on the other hand, though receiving much lower salaries, spend less on their food, or 47 per cent of their income, which adequately provides for their food. This situation would be much improved by an educational campaign.

Earthquakes Recorded at Kew

DURING the period December 1, 1943–February 1, 1944, eight strong earthquakes were registered at Kew. Of these, three were in December, four in January and one on February 1. Two earthquakes were registered on December 1, the first being at 06h. 18m. 50s. G.M.T. from an epicentre tentatively calculated to have been 14,600 km. distant. The maximum amplitude attained at Kew was 26 μ. The second on December 1 was registered at Kew at 10h. 47m. 59s. G.M.T., and this also attained a ground amplitude at Kew of 26 μ. Its epicentre has been calculated by the United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association to have been at lat. 20·2° S., long. 68·1° W., which is in south-west Bolivia. Its depth of focus was probably near 100 km. On December 23 an earthquake was registered at Kew at 19h. 21m. 32s. G.M.T. and attained a maximum amplitude at Kew of 115 μ. Its epicentral position has been calculated by the United States Coast and Geodetic Survey to have been near lat. 6° S., long. 152° E., which is east of New Guinea. Other earthquakes occurred on January 5 (two), 10, and 16. The earthquake on February 1 registered at Kew at 03h. 27m. 59s. G.M.T., had a maximum ground amplitude at Kew of 1,000 μ; it has already been mentioned in the columns of NATURE as having occurred in Turkey.

Two earthquakes not apparently registered at Kew in any strength occurred on December 21, at 13h. 46·4m. G.M.T., from an epicentre near lat. 13° N., long. 70·5° W., and on December 23 at 15h. 56·0m. G.M.T. from an epicentre near lat. 13·3° N., long. 70·4° W. Both are in the Gulf of Venezuela. These shocks were registered at Tucson, St. Louis, Spring Hill, Georgetown, San Juan, Philadelphia, Burlington, Lincoln, Fordham, Pasadena, Huancayo and Chicago, and their provisional epicentres were calculated by the United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association.

Prof. Alexander Macalister, F.R.S. (1844–1919)

PROF. ALEXANDER MACALISTER, the famous Cambridge anatomist, was born on April 9, 1844, in Dublin, where he was educated at Trinity College. He qualified at the Irish Royal Colleges in 1861, became M.B. at Trinity College ten years later and M.D. in 1876. After acting as demonstrator of anatomy at the Royal College of Surgeons in Ireland, he was appointed professor of zoology, and eight years later professor of anatomy and chirurgery, at Dublin. In 1883 he succeeded Sir George Murray Humphry in the chair of anatomy at Cambridge, and held this post for thirty-six years. He was a prolific writer. Besides his "Text-book of Human Anatomy" (1889) for which he is best known, he was the author of "Introduction to Animal Morphology" (1876) and "Morphology of Vertebrate Animals" (1878) as well as of numerous papers on animal morphology, human anatomy and small text-books for students. He was a man of remarkable versatility, being an able mathematician as well as versed in archæology, Egyptology and draughtsmanship. Like his cousin, Sir Donald Macalister, he was a proficient linguist, having knowledge of fourteen languages. He received many honours. In 1881 he was elected a fellow of the Royal Society. He was made hon. LL.D. of the Universities of Edinburgh, Glasgow and McGill and hon. D.Sc. and senator of the University of Dublin. His name has been attached to the fovea gastrica and the annulus femoralis s. cruralis.

Announcements

ON the joint recommendation of the presidents of the Royal Society and the Institution of Civil Engineers, the Council of the Institution of Civil Engineers has awarded the James Alfred Ewing Medal for 1943 to Group Captain Frank Whittle. The Ewing Medal is awarded annually for specially meritorious contributions to the science of engineering in the field of research.

AT the ninety-seventh annual general meeting of the Palæontographical Society held in the rooms of the Geological Society at Burlington House on April 26, with the president, Prof. H. L. Hawkins, in the chair, it was resolved that the Society's Council be empowered to take such steps as be necessary to mark the approaching centenary of the Society in 1947. A committee has therefore been formed to consider suggestions as to how the occasion should best be commemorated; the secretary is Dr. C. J. Stubblefield, H.M. Geological Survey and Museum, London, S.W.7.

ACCORDING to the *Lancet* of April 8, Brigadier-General Leon A. Fox, director of the United States Typhus Commission, says that more than 1,800,000 c.c. of typhus vaccine supplied to Governments in the Middle East under Lend Lease since last June now are a gift of the United States Government. The Typhus Commission has instructions to make the vaccine available to public authorities wherever typhus epidemics appear. Shipments have gone to Egypt, Persia, Iraq, Cyrenaica, Eritrea, Palestine, Trans-Jordan, Tripolitania, Saudi Arabia and Aden.

IN the course of a review published in NATURE of February 19, p. 207, it was stated that the American Philosophical Society became a local scientific association for Philadelphia after the American Association for the Advancement of Science was formed. This is incorrect. The members of the Society come from all parts of the United States and there are at least fifty foreign members. It holds three general meetings a year, which are attended by members and others from all parts of the country, and is generally recognized as the most distinguished organization in America dealing with all fields of learning.

Radioactivity and the Origin of Life in Milne's Cosmology

ACCORDING to the cosmological theory of Milne, we may either describe events in terms of a time t with a finite past, and Euclidean space, or of a time $\tau = t_0 + t_0 \log \frac{t}{t_0}$, where t_0 is the present epoch on the t-scale, and hyperbolic space. On the t-scale the radius of the material universe is ct, the spiral nebulæ are receding, and the lengths of rigid objects are proportional to t, but spectral frequencies are constant. On the τ-scale the nebulæ are not receding, nor is matter expanding, but spectral frequencies are proportional to t at the instant of emission, the light from distant nebulæ being red because it was emitted long ago. The two descriptions of the universe lead to the same predictions regarding all observable events.

It seems worth pointing out some consequences of this theory for geology and biology. The results of these sciences are most naturally expressed in the τ-scale and hyperbolic geometry. For on the t-scale the year and day are a good deal longer than they were in palæozoic times, and a dinosaur's bones are larger now than they were in life. On the other hand, on the τ-scale the amount of energy needed to raise a given object through a given distance is invariant with time, and mechanics are very nearly Newtonian. The heat conductivity of a gas at least, and probably of a solid, is invariant. On the other hand, the rate at which energy is liberated by subatomic or chemical change is constant on the t-scale, but increases on the τ-scale.

This is readily seen in the case of radioactivity. The decay 'constant' is only constant on the t-scale. Thus of N_0 radioactive nuclei present when $t = 0$, $N = N_0 e^{-\lambda t}$ survive to time t. The radioactivity of a given mineral sample, measured by the number of transformations per sidereal year, is

$$-\frac{dN}{d\tau} = \lambda N_0 \frac{t}{t_0} e^{-\lambda t}.$$

So the 'constant' on the τ-scale varies with t. Thus the 'years' of the geological time-scale based on radioactivity are not sidereal years on Milne's theory. Taking $t_0 = 2 \times 10^9$, the earth has gone round the sun $5{\cdot}55 \times 10^8$ times since a rock of radioactive age 5×10^8 'years' was formed, and $2{\cdot}77 \times 10^9$ times since a rock of age $1{\cdot}5 \times 10^9$ 'years' was formed.

The radioactivity $-\frac{dN}{d\tau}$ of a given piece of rock reaches a maximum when $\lambda t_0 e^{\tau/t_0 - 1} = \lambda t = 1$. Thus for ^{238}U, with $\lambda = 1{\cdot}5 \times 10^{-10}$ (year^{-1}), the maximum will occur at $t = 6{\cdot}75 \times 10^9$, or about A.D. $4{\cdot}3 \times 10^9$ on the τ-scale, when it will be about $2{\cdot}4$ times as active as to-day, though containing less uranium. The radioactivity of rocks containing potassium will increase for a vastly longer period; and still later, elements now regarded as stable may show an activity appreciable on the τ-scale, and having appreciable thermal effects if conductivity is constant. Of course, these arguments would still hold if the nuclei in question were formed after $t = 0$, $\tau = -\infty$. These considerations have a considerable bearing on the thermal history and future of the earth. The possibility that similar considerations apply to the stars should make us sceptical of certain extrapolations into the remote past and future.

Consider a living organism at a time in the past when t was comparatively small. It had to do work of various kinds. The measure of most types of work on the τ-scale is independent of t. But the amount of energy available from a chemical reaction such as an oxidation, or the breakdown of adenosine-triphosphoric acid, the immediate source of muscular energy, was not constant. Presumably the energy yield of a given molecular transformation varies with t like that of a given atomic transformation. Thus, in the past, chemical change was less efficient as a source of mechanical energy than it is to-day. Further, the rate of unimolecular breakdown of an enzyme-substrate compound such as myosin-adenosine-triphosphoric acid is sometimes at least the limiting factor in biochemical reactions liberating free energy. If the unimolecular 'constant' is k on the t-scale, it is $\frac{kt}{t_0}$ on the τ-scale, as with the 'constant' of radioactive decay. Thus the actual rate of energy liberation may be expected to vary as t^2.

If so, at a sufficiently early stage, a living organism would have been unable to provide even the small energy needed for cell division or amœboid movements. At a later time, life of a simple sort would have been possible, but locomotion would have been very difficult, and large swimming or crawling animals could not have existed.

Thus on Milne's theory we should expect, first, that life could not originate until a considerable fraction of time on the t-scale, and therefore almost all eternity on the τ-scale, was past, and secondly, that large and fairly complex motile animals should not have originated until a much more recent date. For even when $t = \frac{t_0}{\sqrt{2}}$, or $\tau = 690{,}000{,}000$ B.C. (late Pre-Cambrian), energy for motion would only have been generated at half its present rate. Further, in the remote future, even if the universe degenerates towards thermal equilibrium, or cold matter plus low-frequency radiation, the mechanical efficiency of chemical processes may so increase that life is still possible.

More or less analogous, though sometimes opposite, conclusions follow from other theories, such as those of Eddington and Dirac, in which the fundamental parameters of physics vary with time. These theories are at least possibly true, and biologists who are interested in the remote past and future of life should be aware of their possible implications.

Nature of the Cation Exchanges during Short-Period Yeast Fermentation

DURING the fermentation of glucose by yeast, Pulver and Verzar[1] showed that potassium was absorbed from the external fluid and released again towards the end of fermentation. Leibowitz and Kupermintz[2] showed a similar occurrence in bacteria (*B. coli*). These workers believed the potassium changes to be

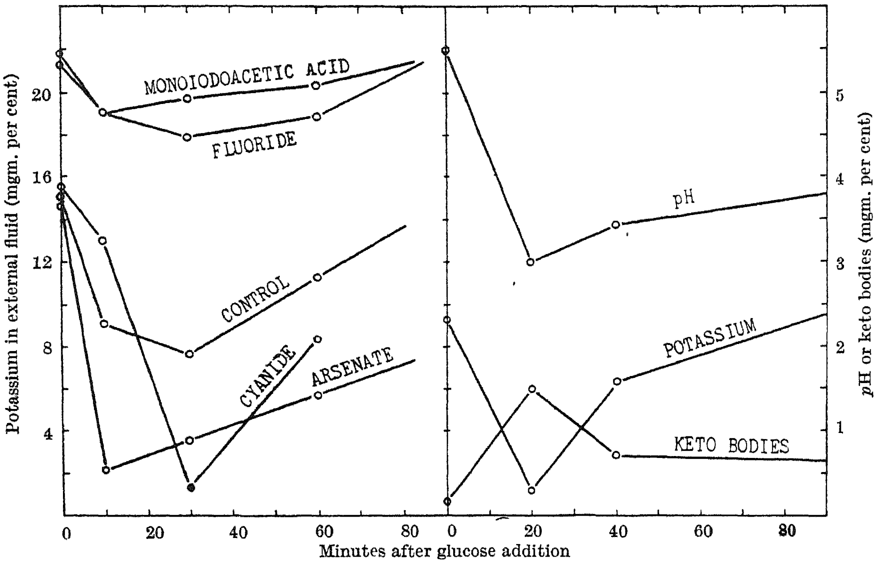

FIG. 1a. 1 VOL. YEAST, 3 VOL. $M/200$ KH_2PO_4 CONTAINING INHIBITORS IN $M/200$ STRENGTH, MIXTURE ALLOWED TO STAND FOR 30 MIN. AND 0·15 VOL. OF 18 PER CENT GLUCOSE ADDED. FIG. 1b. SAME MIXTURE WITHOUT INHIBITORS.

specific for this ion, but it was shown by us[3] that 'ammonia' yeast in which all the potassium of the cells was replaced by NH_4^+ behaved in a similar way with respect to the NH_4^+ ion. An explanation of the process was advanced in which it was considered that potassium entered with phosphate and, this being esterified, held the potassium inside electrostatically, more potassium entering then to equalize the products of potassium and phosphate ion concentrations without and within. Towards the end of fermentation, this process was presumably reversed, and so accounted for the potassium or ammonium released.

Subsequent investigations here have shown that such an explanation accounts only for a small part of the potassium absorption, and the phosphate that entered did not return like the cations to the external fluid. The fuller explanation would seem as follows. The cations which enter the cell during fermentation appear to do so very largely in exchange for hydrogen ions formed by the dissociation of pyruvic acid (or phosphopyruvic acid) formed towards the outer edge of the cell.

The evidence on which this is based is briefly as follows:

(*a*) The change of hydrogen ion concentration in the external fluid synchronizes fully with the potassium ion change (as shown in Fig. 1*b*), and the titration of the external fluid back to the original hydrogen ion concentration more than accounts for the potassium absorbed.

(*b*) The liberation of the hydrogen ion is due to pyruvic acid formation, since inhibitors which prevent its formation, for example, fluoride and monoiodoacetic acid, greatly depress the potassium absorption or the hydrogen ion formation (Fig. 1*a*), and monoiodoacetic acid more than fluoride. Also the analysis of the yeast and of the external fluid shows changes in keto acid formation which are likewise synchronous with the potassium and hydrogen ion changes.

(*c*) The interchange of potassium and hydrogen ions as a movement towards equilibrium is supported by the fact that if no potassium is present outside before fermentation, comparatively large amounts come out when glucose is added, thus reversing the direction of the potassium passage. Also, if the external potassium is raised and the solution outside the yeast cells be maintained as unbuffered as possible (using only potassium chloride and well-washed yeast) the hydrogen ion increases parallel with the potassium increase, and reaches very high levels. On the other hand, if the pH be maintained at 2–5 with comparatively low potassium outside, the proportion of potassium absorbed increases with increasing pH. Such experiments are in strong support of the view that the potassium and hydrogen ions are interchanging as a movement towards some point of equilibrium (or steady state, the movement in itself being conditioned by a fall of free energy).

(*d*) The ratio of the potassium and hydrogen ion concentrations outside is at the same time quite different from the ratio in the yeast cell as a whole, so that the hydrogen ion production would seem to be confined to some part of the yeast cell. When yeast, for example, is first pressed to get rid of as much external fluid as possible, frozen in liquid air, and then thawed so as to release the internal fluid of the cells, this latter has a pH of approximately 5·8. This pH does not decrease if the fluid is extracted from the fermenting yeast cells. It shows rather a slight increase.

(*e*) Supporting evidence for spaces in yeast with different permeabilities is given by the time curve of entrance of urea, and also of ammonia (with carbon-dioxide bubbling as in making the 'ammonia' yeast). Distinct breaks on these curves appear, presumably indicating zones with different permeabilities.

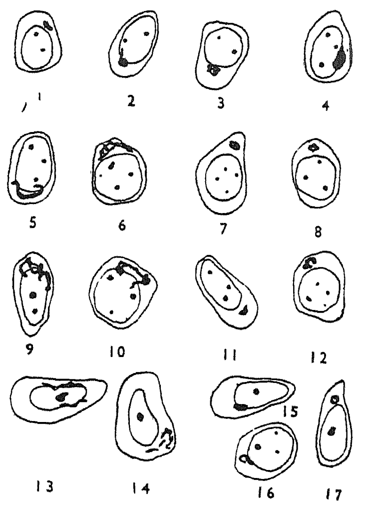
Effect of Colchicine on Golgi Bodies

DURING the course of an investigation on the mitotic activity of the mouse parathyroid gland at different ages[1], using the colchicine technique, very marked alterations in the morphology of the Golgi bodies were observed in material prepared by the Nassonov-Kolachev method. Since the initial observations were made on immature animals, the glands of adult colchicine-injected mice were also investigated.

The results of these experiments are shown in the



1 and 2, cells from 2 days ♀ parathyroid, untreated; 3 and 4, cells from 2 days ♂ parathyroid, untreated; 5 and 6, cells from 12 days ♀ parathyroid, untreated; 7 and 8, cells from 12 days ♀ parathyroid, 0·02 mgm. colchicine for 9½ hr.; 9 and 10, cells from 20 days ♀ parathyroid, untreated; 11 and 12, cells from 20 days ♂ parathyroid, 0·03 mgm. colchicine for 9½ hr.; 13 and 14, cells from adult ♂ parathyroid, untreated; 15 and 16, cells from adult ♂ parathyroid, 0·1 mgm. colchicine for 22 hr.; 17, cell from adult ♂ parathyroid, 0·1 mgm. colchicine for 3 hr.

accompanying illustration. In the case of the adult animals 0·1 mgm. of colchicine was given subcutaneously and the animals were killed at varying intervals after the injection. Immature animals were given a dose in proportion to their body weights and were killed after 9½ hours.

It will be seen from the figures that both the reticulate Golgi bodies of the juvenile gland (Figs. 5, 6, 9 and 10) and the more dispersed and thread-like Golgi material of the adult (Figs. 13 and 14) are affected in the same manner. The effect is particularly striking in the adult gland, where the cells have very varied Golgi-body configurations, probably associated with different states of cellular activity[2,3]. In these instances there is a reduction in size and a marked condensation of the Golgi substance into one and sometimes more granular structures, which frequently assume a ring-like form (Figs. 8, 16 and 17). In one instance (Fig. 17), a marked effect was observed so soon as three hours after injection. This reduction in size and dispersion of the Golgi bodies tends towards a morphological resemblance with those of very young mice (Figs. 1–4).

The effect of colchicine on the mitochondria of parathyroid cells was not so striking, because changes in the extremely small granular mitochondria were not immediately obvious. Most of them, however, were spherical in shape, indicating a marked reduction in the proportion of the rod-like forms normally to be seen in untreated animals. In four instances the duodenum of injected animals was examined and it was found that both the proximal and distal mitochondria of the epithelial cells of the villi were spherical in form; the thread-like type to be found on the distal side of the nucleus was not observed.

It is well known that many substances influence the form of the Golgi material in cells. There are the naturally occurring œstrogenic substances acting upon the cells of the anterior lobe of the pituitary[4] and the uterine mucosa[5]; toxic substances produced in pathological conditions acting on a great variety of cells; and substances foreign to animal tissues such as morphine, which itself has a marked effect on the Golgi bodies of the spinal neurones of rats[6]. In all these instances, above a certain threshold value, the effect consists in hypertrophy of the Golgi element commonly followed by fragmentation. By contrast, the effect of colchicine on the parathyroid is to cause a reduction in the degree of dispersion of the Golgi material, an effect somewhat similar to that produced by the injection of the parathormone itself[7].

Plasma Cholinesterase in Male and Female Rats

Beveridge and Lucas[1] found that the serum cholinesterase activity of mature female rats was three to five times greater than that of mature males or immature females. Similar differences in the cholinesterase activity of rat liver due to sex were also reported by Zeller and co-workers[2]. These reports were made before Mendel and Rudney[3] had established that there are two cholinesterases in the body—one a specific or true cholinesterase, exerting its maximum activity at low concentrations of acetylcholine (about 3 mgm. per cent), and the other a non-specific or pseudo-cholinesterase, capable of hydrolysing other esters besides those of choline and having its maximum effect at high concentrations of acetylcholine (above 300 mgm. per cent). Beveridge and Lucas[1] and Zeller[2] had estimated rat cholinesterase at high concentrations of acetylcholine which would mask the activity of the specific enzyme and thus represent mainly the activity of the pseudo-cholinesterase.

Recently, acetyl-β-methylcholine and benzoylcholine, specific substrates[4] for true and pseudo-cholinesterase respectively, were used to determine the activities of these two enzymes in the plasma of albino rats, and the values obtained were compared with the activity of the plasma towards acetylcholine. Average results for three groups of rats, mature females, mature males and immature females, are shown in the accompanying table.

In agreement with the results of Beveridge and Lucas, it is seen that the activity towards acetyl-

Cholinesterase activity of rat plasma.

	No. of animals	μl. CO_2 evolved by 1 ml. plasma in 20 min.		
		Acetylcholine (0·06 *M*)	Benzoylcholine (0·006 *M*)	Acetyl-β-methylcholine (0·03 *M*)
Mature females	12	606·8 ± 203	128·6 ± 49	62·0 ± 8·3
Mature males	13	170·5 ± 25·4	30·4 ± 9·7	51·7 ± 10
Immature females	20	155·8 ± 29·5	30·5 ± 4·9	43·7 ± 8·1

choline is three–four times higher in the mature females than in the other two groups. The activity towards benzoylcholine, being about four times greater in the plasma of the mature females, parallels the activity towards acetylcholine and shows that the higher activity is due mainly to the pseudo-cholinesterase. Although the differences between the groups in their activities towards acetyl-β-methylcholine are significant statistically, the true cholinesterase certainly would not account for the much higher values found in the plasma of mature females at high concentrations of acetylcholine, since this enzyme contributes little to the activity at these substrate concentrations.

Thus the greater activity of the plasma of mature female rats towards acetylcholine, as compared with that of mature males and immature females, is due mainly to the activity of the pseudo-cholinesterase.

Prenatal Mortality

In the interesting article[1] on "Prenatal Mortality and the Birth-Rate", Dr. A. S. Parkes states, "The amount of prenatal mortality from the time of conception to the time of birth is known to be considerable in many mammals, figures so high as 40 per cent or more having been determined". At least in one mammal, the wild rabbit, a much higher mortality has been recorded, and investigation has shown that with the technique normally employed the full extent of mortality may be overlooked.

It was estimated in a recent paper[2] that the prenatal mortality in wild rabbits in Caernarvonshire in 1941 was not less than 45–58 per cent. More recently[3], with much more extensive supplementary data obtained in 1942, it has been shown that the prenatal mortality approximated to 64 per cent. Of this enormous mortality, 60 per cent is accounted for by the total loss of whole litters about the twelfth day of gestation. The remaining 4 per cent represents a sporadic loss of approximately 10 per cent of the ova in the surviving litters. Further work in progress is designed to show whether this mortality is general in other areas.

The prenatal mortality in polytocous animals is estimated normally by comparing the number of corpora lutea in the ovaries with the number of macroscopically visible embryos in the uterus. This is possible because, as a rule, embryos that die are reabsorbed *in situ*, without disturbing the course of gestation of the remaining embryos. Abortion is a common sequel to embryonic death in monotocous animals, but in polytocous animals it occurs rarely, unless the embryos die near full term. However, if all the embryos in a polytocous animal die almost simultaneously and are reabsorbed *in situ*, the effect on the estimate is much the same as if they were aborted, for once the re-absorption is complete, the mother, being no longer pregnant, would not be included in the sample on which the estimate is based. Hence litters lost in this way would be included in the estimate only if the embryos were actually in process of re-absorption at the time of examination. Consequently, estimates of prenatal mortality, based on counts of corpora lutea and embryos in samples including all visible stages of pregnancy, are liable to be extremely misleading. For example, such an estimate, from the rabbit data referred to, would disclose a mortality of only 24 per cent.

The loss of whole litters in this way can be detected and estimated by dividing the data, according to the stage of development of the embryos, into groups, each of which covers a period nearly commensurate with the time required for the complete re-absorption of a dead embryo of that stage, and by estimating the mortality in each group separately. Clearly, if a significantly higher mortality is found in any of the earlier groups than in the later groups, it can be accounted for only by postulating the loss of whole litters and their disappearance from the samples comprising the later groups; because the corpora lutea persist throughout gestation, and the discrepancy between the number of them and of embryos represents the whole of the loss of ova in that animal from the time of ovulation.

Unfortunately, this method of fractionation requires extensive data and is laborious; but it is clear that until the method has been applied to polytocous mammals, other than the rabbit, it is unsafe to conclude that prenatal mortality in them does not exceed existing estimates and that the loss of whole litters is not of more frequent occurrence than has been supposed hitherto.

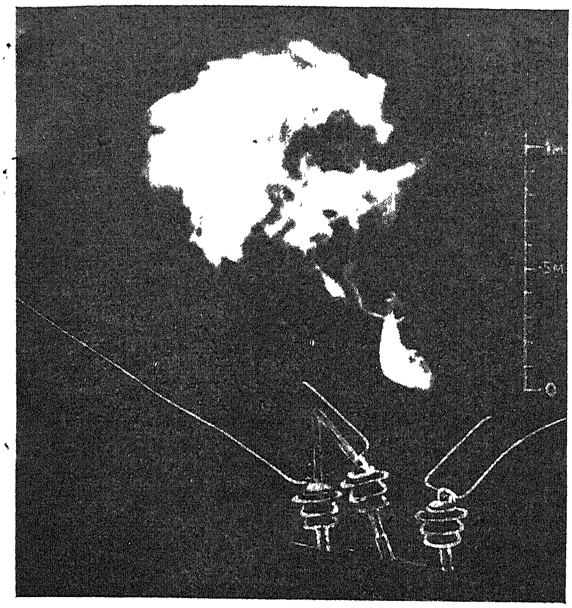
Diffusion Phenomena in Alternating Current Arcs

The successful interruption of large currents at high voltages has been the subject of considerable research, the general aim being to bring about a low-energy release in the circuit breaker by having a short arcing period. During recent years, attention has been focused on the use of a high-velocity blast of gas to effect consistently rapid interruption and at the same time avoid setting up destructive voltage surges in the circuit. Numerous oscillograms have shown that final interruption takes place towards the end of a half-cycle, and for this reason great interest has been taken in the de-ionizing influences which are active immediately after current zero.

While it is generally agreed that diffusion enhances the recovery of dielectric strength during at least the first 10 microseconds after the recorded current zero, there are differences of opinion as to the mechanism which is mainly responsible for avoiding the re-striking of the arc. By suitable mechanical arrangements[1], a gas blast can be so directed that some time after current zero a wedge of cold gas is inserted in the arc trace. This wedge extends rapidly and can



EXTINCTION OF 10 KV., 280 AMP. ARC. EXPOSURE TIME, 1/400 SEC

be thought of as a major factor in building up dielectric strength. Slepian[2] has strongly criticized this point of view, and has argued that diffusion rather than displacement is the vital factor in circuit interruptions.

Some information on the nature of the processes at work after current zero has been obtained by large-scale experiments with 50-cycle arcs in open air. By drawing arcs of 100–320 amp. at 10,000 volts, highly unstable conditions were obtained which gave rise to extinction in times of the order of 1 second.

Numerous photographs were taken to examine the progressive nature of arc instability and one of these, taken shortly after final interruption, is reproduced. This seems to indicate that interruption takes place at one pole earlier than the other and that the final current is a space-charge-limited discharge. Other photographs show that separate clouds of excited atoms or molecules can exist for appreciable times after current has been interrupted.

A fuller account is in course of preparation.

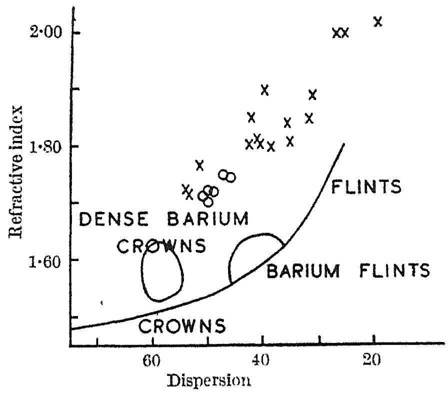
New Types of Optical Glass

The communication[1] by Messrs. Hampton, Bastick and Wheat is timely in that it directs attention to recently developed forms of optical glass that depart markedly in properties from those previously available and so provide optical designers with increased scope. Two statements, however, need correction. The refractive index limits of the new Kodak glass[2] are 1·71–2·02 and not 1·71–1·97, as stated; while the reference to the Kodak glass (known as *EK*2), having $nD = 1{\cdot}745$ and $V = 45{\cdot}8$, should not be taken to imply that it is now generally available. This glass is being made in England in our laboratories under the ægis of the Government and can be supplied for war purposes only.

The full range of optical properties now capable of realization as a result of our researches in the manufacture of glass from rare earth elements, with little or no proportion of silica, is shown in the accompanying figure. In support of the suggestion, by Hampton *et al.*, that the availability of glasses of such outstanding properties should stimulate work in lens design, it may be mentioned that many patents on lens design have been granted since the publication of our patents[2]; for example, B.P. 517,271; 523,061; 523,062; 535,501; 548,254; 548,255; 548,256; 548,251; 547,691; 554,291; 555,464; 555,404, to mention but a few. Some stimulation of lens design has, therefore, already occurred. Indeed, the Eastman Kodak Company was supplying lenses using the new glass before the present War, and is now using it in air-camera lenses on a large scale.



COMPARISON OF NEW KODAK GLASSES WITH OLDER TYPES. × REFERS TO GLASSES DESCRIBED IN B.P. 462,304: ○ REFERS TO GLASSES DESCRIBED IN B.P. 534,680.

So far the chief demand has been for the *EK*2 type; but we shall welcome any expression of views that will assist us in deciding which of the other members of the series should be made available.

A Deluded Sparrow

We have been much intrigued of late by the actions of a cock house sparrow which has apparently become permanently attracted by its own reflexion in a glass window. The window forms a transom over a door and we first noticed the bird flying at the glass and pecking it violently. When this was continued for a long period, closer observation was made and the available facts collected. At the time of writing, the observation period has extended over more than a fortnight, and the bird shows no sign of deserting its post. The facts are as follow:

(1) Although there are many windows available in the immediate neighbourhood, attention is confined to one piece of glass. (2) Although the bird sometimes

absents itself during the day and always at night, it returns to the same place. We have not been able to discover its night resting place. (3) A piece of mirror was fastened to the outside of the glass by means of two bright 3 in. optics pins stuck into the frame. The mirror was loose behind the pins and the nature of the restraining force would be clear to a creature with intelligence. The presence of the mirror much excited the bird, and it made violent efforts to get behind the mirror. To do this it seized the pins in its beak and pulled. On two occasions it managed to remove the pins. (4) Occasionally during the day, regularly at about 8.30 a.m., it fetches pieces of food and tries to push them through the glass. The food is obtained nearby, where tits and chaffinches are fed daily. There are not many house sparrows on this particular feeding ground. (5) The bird shows considerable boldness, for people are constantly passing within a few feet of it. It made attacking rushes towards me when I was fixing the mirror in position. (6) At times the bird becomes tired and rests, sometimes on a small projection above the window, more frequently huddled close to the glass. When the mirror was in position it usually chose to huddle close to the mirror. In both these resting places it often utters its song.

We are interested in the implications of this evidence. In the first place, the deliberate and repeated efforts to remove the pins holding the mirror argues a certain amount of intelligence. Secondly, why should this bird ignore the available real birds which have the auxiliary attractions of smell and song and devote itself to a faint visual image? Surely this action cannot be purely instinctive. It argues a mental maladjustment; but this postulates the possibility of intelligence well above the instinctive level.

Wordsworth and Science

WORDSWORTH's apparent antipathy to science, as revealed by the quotations which Dr. Wigglesworth has given in NATURE of March 25 from his poetical works, has always provoked adverse comment, not unnaturally, from scientific men, and the quotation which has so long adorned the front page of NATURE has always borne a somewhat ironical air.

Yet it would seem that Wordsworth once had high hopes of science, and those who have read his famous introduction to the "Lyrical Ballads" will find there a more sympathetic view of it and, incidentally, a statement of what Wordsworth conceived to be the relationship between science and poetry. That relationship touches the crux of the matter, however we view it, but I do not propose to discuss it here. But it may be pointed out that when Wordsworth was writing, science had elaborated few of those great generalizations with which we are now familiar and which have some claim to be regarded as imaginative efforts paralleling those of the poet and artist.

It would also appear that Wordsworth's strictures were provoked less by science itself than by a certain narrow-mindedness he had found in 'scientists' of a sort with whom he had come into contact. His animadversions may not have been altogether undeserved; scientific workers of a certain type and calibre do not always exhibit in their mental outlook the fruits of a liberal education, assuming they have had one, and their attitude to poetry and the arts may be as unsympathetic and naïve as that which Wordsworth often displayed towards science. There was some ground for his revulsion from the cold detachment of science when the pursuit of it deadened the wider sensibilities of some of its followers. If poetry and the poets have their vapourings on occasion, science and the scientists have equally their aridities and myopic crudities.

H. A. SCRUTON.

"The Ridings",
Riplingham Road,
Kirk Ella,
E. Yorks.

MR. SCRUTON's comments, with which I am in entire agreement, afford me an opportunity of making good an omission from my article. I omitted to state that my notes were limited to Wordsworth's poetical writings. The omission is indefensible; but the limitation I think can be defended, for Wordsworth's prose writings are immeasurably inferior to his poetry—as he himself surely felt when he hesitated whether to reprint the prefaces, and decided to include them at the end of his last volume where they could be read or not as the reader might desire.

As Mr. Scruton rightly says, the references to science which the prefaces contain are certainly more sympathetic. "The knowledge both of the Poet and the Man of science is pleasure". But still "Poetry is the breath and finer spirit of all knowledge; it is the impassioned expression which is in the countenance of all Science." Wordsworth concedes that "the remotest discoveries of the Chemist" may be "proper objects of the Poet's art" and "if the time should ever come when what is now called science . . . shall be ready to put on, as it were, a form of flesh and blood, the Poet will lend his divine spirit to aid the transfiguration, and will welcome the Being thus produced, as a dear and genuine inmate of the household of man". As Mr. Scruton asks in effect, if Wordsworth were alive to-day, would he have judged that that time had now arrived?

V. B. WIGGLESWORTH.

The Rare Gene Rh_y in Mother and Son

Wiener[1], and Race *et al.*[2,3,4], have independently described allelomorphs of the *Rh* gene. In addition to the six common to both investigations, the possession of the *St* serum enabled Race *et al.*[3] to define a seventh rare allelomorph, Rh_y.

The first family evidence that Rh_y is allelomorphic has just been obtained from the examination of the parents of the first Rh_1Rh_y donor recognized. His mother was Rh_1Rh_y, and his father's blood gave the reactions of Rh_1Rh_2. Three different sera of the *St* type were used in testing this family.

TECHNICAL EDUCATION OF THE FUTURE

Dr. D. S. Anderson, principal of the Birmingham Technical College, recently addressed a meeting of the Birmingham General Branch of the Association of Scientific Workers, outlining his views on desirable changes in technical education in Great Britain.

Technical education, Dr. Anderson said, may be roughly defined as the education required by, and given to, personnel in industry, this personnel ranging from the skilled craftsman to the man doing laboratory development work of the highest character. At present the personnel of industry falls roughly into four groups: unskilled, semi-skilled, skilled and technical staff workers. Before examining the needs of the different groups, one should consider if any change in the grouping is to be expected in the post-war period. Dr. Anderson thinks such a change is to be expected. The increase of mechanization, of automatic processes and control, of scientific in place of empirical bases for much industrial practice, will all increase considerably the number of technical staff workers required. This development will be accompanied by the de-grading of many skilled operations to semi-skilled, and the net result is likely to be a decrease in the number of skilled workers and a corresponding increase in the number of technical staff workers and semi-skilled workers. While many may deplore the diminution in the number of skilled workers, the change really represents an advance.

The teaching institutions are concerned only with the skilled and technical staff workers. In Great Britain, apart from university degree courses, comparatively little special preparation or training is given before entering industry. Both the practical and theoretical training begin after entry, the theoretical training being taken, in the majority of cases, in the form of evening courses. This present system of training is unsatisfactory in three main respects: the system is slow, it is frequently unorganized at the works end, and the evening study imposes a very heavy burden on the young person. Students are frequently engaged on their technical studies right through their early twenties, and as a result of this prolonged period of technical study are prevented from developing an interest in cultural subjects and social affairs. One of the main post-war tasks in technical education should be an endeavour to shorten all forms of technical training. In the case of the skilled worker, this could be done by more systematic training in the works, and in the case of the technical staff worker it might be done by arranging some part of his technical course on a full-time basis, either at the beginning or end of the training period. On the Continent, full-time courses for technical staff workers prior to entering industry have been developed to a considerable extent and have proved of great value in supplying industry with a body of well-trained technicians.

Another post-war problem is concerned with teachers in universities and technical colleges. The quality of instruction in any teaching institution depends first on the teacher, secondly on the equipment, and thirdly on the building. While it is obvious that teachers must be carefully selected initially, very little has been given in the past for what one might call their 'care and maintenance'. The output of new knowledge in all branches of science and technology is so overwhelming that teachers have the greatest possible difficulty in keeping up to date. Technical teachers therefore require refresher courses to bring them up to date in their subjects, and periodical returns to industry to be brought up to date in industrial practice.

Two other points concerning teaching are that some subjects are best taught by practising specialists, and therefore firms should be prepared to allow senior members of their technical staff to act as part-time lecturers during the day. The other point concerns exchange of teachers. It would have a very stimulating effect if teachers could be exchanged between institutions such as universities and technical colleges, and also with American and Dominion institutions.

One of the problems which is ever present in a teaching institution is that of getting into a syllabus all the subject matter which is required. The boundaries of knowledge are advancing so rapidly in all directions that material has constantly to be added to all technical and scientific syllabuses, causing most serious overloading. Perhaps the best solution for this problem is for the universities and technical colleges not to attempt too much in their normal courses, and then to offer, after graduation, a wide range of special advanced courses for technical men in industry to take as required. If some such action were taken and the normal courses relieved of some of their present congestion, it might be possible to introduce a few 'liberal' subjects into these courses, and so remove the frequent and merited reproach that technical courses are too narrow.

RELATION OF ACADEMIC TRAINING TO INDUSTRY

The Swiss university journal *Schweizerisch Hochschule Zeitung* of September 1943 contains some long extracts from a report by Dr. H. Erb which has attracted considerable interest in Switzerland, and may have some bearing on post-war educational problems in other countries. It deals with the old and recurring problem of too many with academic training, a matter which has also exercised the minds of leading educationists elsewhere, notably in Germany a few years ago, when it filled many columns in the *Chemische Zeitung*, and also in the United States. The pressing needs and special conditions of war have submerged the problem in most countries to-day; but it is likely to emerge with still greater insistence after the War. Dr. Erb, while analysing its special features under Swiss conditions with much detail, does not suggest any very new or striking remedial or preventive measures other than those which have already been frequently urged in Great Britain and America: such, for example, as the warning against excessive concentration on the vocational side of education, at all events in a too narrow or specialized sense; the urgent need for raising the dignity of handiwork, of applying more thoroughly the doctrine of Morris and Kropotkin of mind-training through the hand; and a few generalities briefly dealt with below. So far as Switzerland is concerned, it is thought that more complete statistics and better analytical interpretation thereof, together with a greatly improved central organization for the transfer of university men into suitable openings in industry, are urgently needed.

If the number of young people leaving school and college is much larger in recent years than at the beginning of the century, it would seem that this is less marked in Switzerland than in certain other countries. For example, it is pointed out that, in 1930–31, per 100,000 of population, Germany had 63 *Abiturienten* (holders of school-leaving certificates or equivalent) whereas Switzerland had only 34. Japan and Rumania in 1934 had more than six times as many with academic training as in 1913. In the same period those of Holland increased by 146 per cent, of France 112 per cent, of Great Britain 83 per cent, and of Switzerland 59 per cent. According to Dr. Erb, the most disturbing aspect of this increase in quantity is the serious decline in quality: he thinks the standard, however measured, is definitely lower. The real problem, therefore, is not necessarily 'too many', but 'too many of the wrong type'. Mediocrity is said to be very noticeable in the universities and secondary schools. There are far too many *Brodstudenten*, or those who concentrate too closely on the vocational side to the neglect of the broader cultural and intellectual aspect. They specialize too soon and aim at passing through the technical schools as quickly as possible. The sole business of education, in their view, is to enable one to earn a living in some narrowly specialized sphere. We are faced again with the dangers of specialization, which have been debated *ad nauseam* in recent years.

Dr. Erb may have put his finger on one of the main sources of the trouble when he admits that school-building accommodation and number of teachers have not kept pace with the increased number of entrants. Teaching has become less individualistic than ever, and tends to savour of mass-production methods. It is difficult, of course, to be precise on this matter of quality; but both in the universities and in industry there are complaints that, despite the large increase in number of those with academic training, there is serious lack of the right type for the needs of industry and trade. If sufficient school space is wanting; if there are too few teachers and these are underpaid, with inadequate status and insufficient knowledge of the needs of business and industry, then the quality of the students must necessarily suffer. Certain it is that many of them show signs of hurried and inadequate training, both of mind and character—especially the latter: they are incapable of adapting themselves readily to the realities of life, from which they expect too much.

Although Dr. Erb complains that educational, or at least academic, statistics are not so good as they might be, and those which are available are not intelligently used, he thinks there is little doubt that the number of entrants to schools and universities tends to increase considerably in periods of industrial prosperity; but by the time these new entrants have finished their scholastic career, the boom period has been succeeded by depression, and they are condemned to unemployment; so much harder to bear in proportion to their academic qualifications. This is one of the tragedies of unemployment, raising larger issues than can be dealt with here; nevertheless, it must be remembered that, as already indicated, chances of employment for those with academic training—even in lean times—would be increased if they were more adequately or properly trained.

Reference is made also to the impact of social conditions and changes on the relative numbers of students at secondary schools and universities. The rights of man and consequent social philosophy of the nineteenth century led to the emancipation of the lower classes and of women, and to increasing demands for improved social status and better education. Dr. Erb considers that, in Switzerland, the exaggerated importance imputed to academic learning of the more showy or superficial type was particularly marked, and was closely associated with the growing social prejudice for black-coated respectability. Those who had not themselves attained to this status were anxious and determined that their children should do so; and this delusion, says Dr. Erb, will continue until it is more generally realized that the harder one studies the more certainly will he miss the road to wealth. This may be often true, but scarcely attains the dignity of a general proposition; and in any event strikes a slightly discordant note in its present context.

Among remedial measures suggested are a more careful selection of candidates for the school-leaving examinations, and greater attention to the importance of test or observation periods rather than exclusive concentration on examination results. In other words, the examination system is again under criticism, as is frequently the case to-day. Dr. Erb is strongly of opinion that the path to the university should be more strictly reserved to those above the general average who can best profit by university training. Not only should the school-leaving examinations (*Maturitätsschule* and *Auslese*) be considerably tightened up and revised, but also they should be supplemented by a system of character tests and observation periods, so that the real abilities of the student, not necessarily brought out by the usual examination, could be much more clearly and thoroughly ascertained. The examinations themselves should not usually be made more difficult in the sense of book knowledge—they are already too overloaded—but rather should include tests of character and personality not generally provided for in the examination papers.

CORRELATION OF THIXOTROPIC SETTING WITH DENSITY IN SILVER AMALGAMS

By DR. D. R. HUDSON
Heriot-Watt College, Edinburgh

SILVER and mercury form, by peritectic reactions at 276° and 127° C. respectively, intermetallic compounds represented very nearly by the formulæ, $AgHg$ and Ag_3Hg_4. They exist in space lattices of the close-packed hexagonal type with $a = 2 \cdot 987$ A., $c/a = 1 \cdot 62$, and the body-centred cubic type with $a = 10 - 10 \cdot 1$ A., respectively; the latter resembles the well-known γ-brass structure, but is not identical with it. In synthesized amalgams the range of stability of both species is small, probably not exceeding $\pm \frac{1}{2}$ per cent. Ag_3Hg_4 exists as native amalgam (argental or landsbergite) often in very well-formed crystals in the cubic system, corresponding closely in composition to the artificial product; $AgHg$ has not, so far, been reported in minerals, and Heide has suggested that this species does not occur native. Further, Ag_3Hg_4—known already to the alchemists as *Arbor Dianae*—can be obtained chemically by displacement of ions of either metal in solution by the action of the other. This is in accordance with the fact that the two standard

electrode potentials are almost identical: 0·799 v. for $Hg : Hg_2^{\cdot\cdot}$ and 0·798 v. for $Ag : Ag^{\cdot}$ at 25° C. In the hardening of plastic dental amalgams, Ag_3Hg_4 is formed by the reaction

$$\underset{\text{filings}}{Ag_3Sn} + \underset{\text{liquid}}{Hg} \rightleftarrows \underset{\text{dendrites}}{Ag_3Hg_4} + \underset{\text{solid solution}}{Sn(Hg)}$$
(Black, Troiano)

Densities of heterogeneous silver amalgams. The variation of density with composition has been determined for the heterogeneous range. Although the solubility of silver in mercury is small—only about 0·03 per cent at room temperature—they are quite fluid up to about 8 per cent. Between about 8 per cent and about 20 per cent silver, they are plastic on formation but 'set' on standing overnight; above 20 per cent they resemble hard 'Plasticine' rather than a heterogeneous mass, becoming gradually harder as the composition of the solid amalgam is approached. This was found to be 27·43 and 27·72 per cent in two separate experiments, by expulsion of the liquid phase (argentiferous mercury) under severe compression. By very careful handling of the set amalgams, it was found possible to use Archimedes' method down to about 13½ per cent silver; below this a special midget (2½ ml.) specific gravity bottle was used with success. The results are in fair agreement with the older determinations of Mey (1905), but are more consistent among themselves and probably rather more accurate than these; the very erratic values reported by Joule (1863) and Duczko (1935) were not confirmed. The density/composition curve shows small but distinct peaks at about 15 and 28 per cent, about 13·61 and 13·60 respectively, with minima at about 13 and 25 per cent, that is, 13·47 and 13·37. Between these points the curve is made up of straight lines and the *density is invariably above that calculated for a conglomerate* by summation of volumes. The silver content (at the mercury boundary) lies about midway between $(Ag_3Hg_4)_4$ proposed by Weryha (28·74 per cent), and $(Ag_2Hg_3)_{10}$ proposed by Berman and Harcourt (26·4 per cent), but a Hume-Rothery constitution $(Ag_5Hg_8)_4$ is definitely excluded by present results as well as by *X*-radiological and metallographic data.

Setting and Thixotropy. The amalgams set like plaster of Paris when they contain more than 8 per cent silver, but the process is very different, being completely and repeatedly reversible by pressure alone. During setting, the hardness increases; above 20 per cent one can obtain a robust mass which becomes quite plastic on kneading. This process is thixotropic, being due to the formation of a well-defined *réseau* of acicular crystals, which is quickly degraded under local pressure. Surplus mercury is held in this spongy structure as a result of its high surface tension, and in the mercury-rich amalgams may be seen to liquate out, leaving the dry *réseau* intact. It is rare to find thixotropy displayed so perfectly as in these amalgams.

Effect of setting on density. With the incidence of setting there is also a fall in density of 1–1½ per cent in a few days. In an extreme case, a 15 per cent alloy, which had stood undisturbed for more than two years, segregated into hard discrete equi-axed lumps and argentiferous mercury. Hard grinding was required to restore this to the plastic state, when its density was found to be normal and as much as 4 per cent greater. This ('pea' plus liquid) state is regarded as the ultimate limit of thixotropic setting, equivalent to complete spheroidization of cementite in steel. Two explanations are suggested.

(1) That pressure causes Murphy's peritectic reaction at 127° C. to go leftward at room temperature. $\beta + Hg \rightleftarrows \gamma$, or very nearly $3AgHg + Hg \rightleftarrows Ag_3Hg_4$.

(2) That the *réseau* consists of another intermetallic species, formed on standing and restored on kneading to the Ag_3Hg_4 originally present. This species might be either the same phase (27·7 per cent silver) in another space lattice with different physical properties, or a new intermetallic compound, possibly of different composition. Unfortunately, the relative proportion of jagged crystals and argentiferous mercury in the 15 per cent amalgam was not determined accurately. It may be estimated to be about 1 : 2, which would give an approximate silver content of about 45 per cent, the solubility of silver in liquid mercury being very small at room temperature. One may recall Murphy's β-constituent containing about 40 per cent mercury, which we have denoted AgHg.

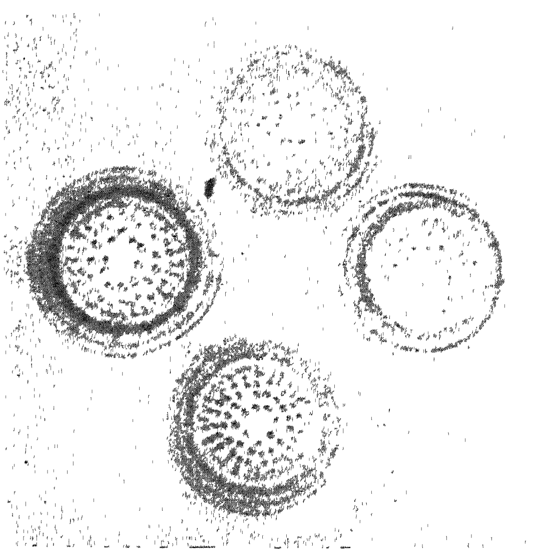
Dental amalgams. The unexpectedly low density of the set structure (spongy *réseau* plus argentiferous mercury) accounts very happily for the paradoxical expansion of tooth stoppings too rich in silver—a sharp change in setting characteristics takes place at 25·5–26 per cent. This bugbear led to the postulation of void formation by Gray, which *faute de mieux* has been accepted by Troiano and Gayler. However, in the specimen mentioned, in which the thixotropy had proceeded to the extreme limit, the measured difference of 4 per cent in density would require a void volume of as much as one eighth in the 'peas'. In view of their hardness and jagged nature, this is very difficult to accept. Moreover, it is somehow repugnant to scientific intuition to believe that voids can be formed on dendritic crystallization within a mother liquor with surface energy as high as mercury. Sullivan's amalgam of precipitated copper and mercury, now discarded in dentistry, is plastic but sets *hard* in a few hours, and can then be rolled or hammered. On kneading or heating, the mass recovers its plasticity.

Application to other physical properties. It is formally suggested that other anomalies in the physical properties of amalgams of alkalis and other metals, for example, viscosity, surface tension, electrical conductance, may also be due to thixotropy rather than to colloid formation.

A SIMPLE TECHNIQUE FOR PHOTOMICROGRAPHY

By Dr. W. N. LEAK

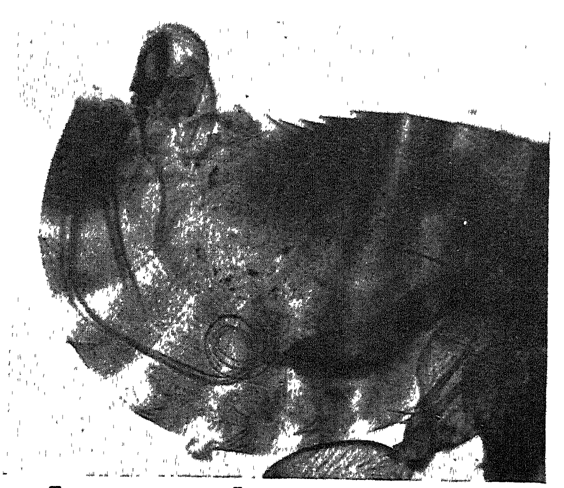
No record of a microscopical preparation can compare in value with a photograph, yet photomicrographs are often not taken so frequently as workers might wish because of the difficulty of doing the work personally or the interruption caused by sending it to a special photomicrographical department. There is, however, a simple method of obtaining excellent photomicrographs. The method depends on the fact that a camera will photograph a virtual image as easily as it will a real object. The image in a microscope is a virtual one, and if this is focused, as it normally is, at infinity, and a camera, also focused at infinity, is placed as near as possible to the ocular, so that all the light coming through the ocular enters the camera lens, a good photograph will result if the exposure is correct and the camera truly in line with the microscope tube. In actual practice this can be judged sufficiently well by eye,



Cestodiscus superbus. MEDIUM POWER (½ IN.). F.P.2 FILM. × 600 APPROX.

and the actual taking of a photomicrograph by this method presents no real difficulty whatever. We can ensure that the microscope image is focused at infinity either by using a focusing screen or a reflex camera, but much more simply by viewing part of the image through a small telescope (a 4-in. lens with a spare eyepiece in a cardboard tube makes quite a satisfactory one) focused for infinity and altering the fine adjustment until the image is sharp. Even this simple procedure is not necessary if the observer's eye is quite normal.

The excellence of the results obtained by this method seems to be due to two factors. First, practically all microscopes are constructed to give their finest results when used visually with an eyepiece, etc., and these conditions do not obtain in the ordinary methods of photomicrography. In the present method, however, we make the microscope give the finest visual image of which it and we are capable, and then photograph this image with the best photographic equipment at hand. The second reason is that in the ordinary way there is a considerable distance between ocular and plate, and this is liable to give rise to serious diffraction phenomena.



TAIL OF MALE FLEA. LOW POWER (1 IN.). H.P.2 FILM.

In this method, however, the length of these narrow pencils of light is scarcely greater than the focal length of the camera lens, so that diffraction troubles almost cease to exist.

With a 10-in. camera lens, the image on the film will be the same size as that seen by the eye, and such a film should stand considerable enlargement, though actually I find that my Leica with a 2-in. Elmar lens will reproduce practically everything I can see if fine grain film is used and enlarged about eight times. To illustrate this the photograph of *Cestodiscus superbus* was deliberately taken at the lowest visual magnification to show the marginal striations comfortably and the film enlarged eight times. A 4-in. or 5-in. lens might be better for general use, though longer exposures would be required. Kodachrome or Agfacolor film have even finer resolution than fine-grain film. With this method there is nothing to prevent the use of high-power eyepieces, for the close eyepoint and the shadows on the retina of blood vessels and opacities, etc., which make them objectionable for visual use do not affect the camera lens. I do not imply that this will give resolution beyond the resolving power of the objective, but it may well show details on the enlarged print which many eyes would fail to see visually.

I hope this brief description of some of the practical and theoretical points involved will make the method better known, for it has great possibilities in industrial and academic research, as well as in teaching. The method can naturally also be used for obtaining a photograph through any other instrument which uses an eyepiece, such as telescope, spectroscope, etc. A fuller description of the method appeared in the *British Medical Journal* of December 18, 1943, p. 787.

SOME SOUTH AMERICAN TIMBERS

TWO Leaflets, Nos. 31 and 32 (September 1943), have been issued under the auspices of the Department of Scientific and Industrial Research by the Forest Products Research Laboratory on "Some Foreign Timbers (South America), 3 and 4" respectively. The leaflets deal with the tree, timber, seasoning and mechanical properties, natural durability, insect attack, preservative treatment, working qualities, uses, and supplies available.

In Leaflet No. 31 two trees, the parana pine, *Araucaria brasiliana* and louro vermelho, probably *Ocotea rubra*, are discussed. The parana pine is a sub-tropical conifer attaining a height of 110–130 ft. with an average diameter of 2 ft. and clear bole of 60–70 ft. It occurs in the Andean region of South America at varying altitudes above 1,600 ft. and preferably on sandy soils. The timber is not resistant to decay, and sapwood very liable to develop a blue stain; it is easily worked by hand and machine tools.

Louro vermelho attains a height of more than 100 ft. and a maximum diameter of 3 ft. in some parts of its range, which probably includes Brazil and British Guiana and may extend further. The timber is said to be resistant to decay, probably more resistant than the heartwood of English oak; a character which, should it be confirmed, is high praise indeed. It is said to be easily workable with hand and machine tools.

Leaflet No. 32 gives notes on peroba rosa, *Aspidosperma polyneuron* (syn. *A. peroba*); and mandio-

queira, Qualea spp. The peroba rosa tree is said to attain a height of 125 ft. and a diameter of 4–5 ft. in the San Paulo State in Brazil. In less favourable parts of its range, however, it is often less than half this size. It is highly resistant to decay and is easily worked by hand and machine tools.

The name 'mandioqueira' refers to several closely related species of Qualea in the Amazon region. In Central and Southern Brazil the same name is applied to species of Didymopanax, with timber of entirely different character. In Brazil mandioqueira occurs as a large tree mainly of the uplands and the banks of running streams. It probably averages about 100 ft. in height at maturity with a diameter of about 2 ft. About thirty species of this genus have been recorded from Brazil and the adjoining countries. The timber is moderately hard to work by hand or machine tools, being somewhat cane-like in its resistance to cutting. It is said to be like the African iroko (*Chlorophora excelsa*) in many respects.

A factor, not without importance in connexion with the research work undertaken by the Forest Products Research Laboratory on these foreign timbers, is in its application among other uses to their suitability or otherwise for plywood conversion.

PETROLEUM: PAST, PRESENT AND FUTURE

THE petroleum supply situation is causing considerable comment in the United States at the present time and no doubt there is the usual crop of rumours concerning imminent scarcity of this product, so necessary in peace-time, so indispensable at this critical period of warfare. Dr. Per K. Frolich has given (*Science*, Nov. 26 and Dec. 3, 1943) a candid picture of the present position, supported by data from a number of reliable sources. Unhesitatingly he states that eventually a shortage in natural petroleum will occur; but he is equally emphatic that when that time comes it should be possible to obtain all necessary hydrocarbon products from alternative sources. Moreover, there is nothing to indicate that there will be any break in continuity of supply of gasoline and other petroleum derivatives. Nothing more nor less is envisaged than the gradual introduction of synthetic products into the industry as the supply of natural hydrocarbons declines.

Methane, the major constituent of natural gas, can be converted into gasoline by the Fischer-Tropsch process, used commercially in Germany for some considerable time; the heavier constituents can be processed by cracking or dehydrogenation, followed by polymerization and alkylation. Oil can be recovered from shales by 'retorting' under suitable conditions of temperature and pressure. The Tertiary deposits of the Rocky Mountain Region, the Devonian black shales of Indiana and Kentucky, and the cannel shales of Pennsylvania and West Virginia represent a large potential supply of liquid hydrocarbons. In 1928 these deposits were estimated by Dean E. Winchester as capable of producing 92 billion barrels of oil. In addition, there are the Canadian deposits of tar sands which spread over thousands of square miles.

These potential reserves of liquid hydrocarbons are, however, insignificant when compared with the quantity which could be produced from coal deposits. H. L. Ickes, Petroleum Administrator of the United States, estimated in August 1943 that available coal reserves can provide all the synthetic fuel needed for a thousand years and still leave enough for present purposes.

So far these alternative sources of liquid hydrocarbons have scarcely been tapped in the United States, whence before the War came 63 per cent of the world's petroleum requirements. Indeed, it is unlikely that they will be exploited to any great extent for some time to come. The next phase of development in the petroleum industry, as envisaged by Dr. Frolich, will be characterized by further technological progress, increased drilling for oil on a world-wide basis and necessary adjustments in supply and demand. All these factors will tend to prolong the availability of natural resources and, when peace comes, fear of their imminent exhaustion will loom correspondingly less large.

BOMBAY ISLAND

THE president of the Section of Geology and Geography at the thirty-first session of the Indian Science Congress at Delhi last January was Dr. A. S. Kalapesi, of St. Xavier's College, Bombay. Appropriately, Dr. Kalapesi chose as the subject of his presidential address a review of the geographical and geological features of Bombay Island. His discourse on its geographical aspects is of much interest to those who know Bombay, especially because in describing the evolution of the present unitary island from the earlier seven separate islands (the *Heptanesia* of Ptolemy) Dr. Kalapesi mentions also the derivation of many of the well-known place names. The word Bombay itself, for example, is now generally accepted as derived from the name, 'Mumba Devi', of the tutelary goddess of the first known inhabitants of these islands, the Kolis.

Geologically, Bombay Island is a portion of the great spread of Deccan Trap lavas occupying so much of Western India, and is composed essentially of westerly dipping sheets of this basaltic formation with a freshwater intercalation, the whole being masked in places by recent sea and lagoon deposits. That there have been geologically recent changes of level is proved by the presence of a raised sea beach in the centre, and of a submerged forest on the east side of the island. The sedimentary bed mentioned above is of special interest as it contains numerous beautifully preserved fossil skeletons of small frogs. The lava sheets of Bombay are thought to be in part of extrusive origin, like the main mass of the Deccan Trap lava flows, and in part of slightly later intrusive origin.

It is evident from Dr. Kalapesi's address and the writings of some of his predecessors (Carter, Wynne and Fox) that what is now needed is a detailed geological study of Bombay Island, including a careful petrographical study of the various rock types, fortified by chemical analyses. At present views differ, for example, on whether the lava flow that constitutes Malabar Hill, whereon is situated Government House and many of the residences of the merchant princes of Bombay, is composed of basalt, andesite or trachyte. There should be no room for doubt on such a point as this. The task suggested seems a suitable one for geological residents of Bombay, such as Dr. Kalapesi and his students.

L. L. FERMOR.

FORTHCOMING EVENTS

Monday, May 8

SOCIETY OF CHEMICAL INDUSTRY (PLASTICS GROUP) (at the Waldorf Hotel, Aldwych, London, W.C.2), at 2.30 p.m.—Annual General Meeting. Mr. H. Langwell: "The Technique of the Scientific Lecture".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8 p.m.—Mr. K. de B. Codrington: "Valleys of the Hindu Kush".

Tuesday, May 9

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Prof. H. J. Fleure: "Some Islamic Reactions to Modern Life around the Eastern Mediterranean".

ILLUMINATING ENGINEERING SOCIETY (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 5 p.m.—Annual General Meeting. At 5.30 p.m.—Sir Charles Darwin, K.B.E., F.R.S. "Tolerances and their Effect on Physical Measurements".

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London S.W.7), at 6 p.m.—Mr. David Charles: "Practical Cure of Convergent Verticals".

Wednesday, May 10

SOCIETY OF CHEMICAL INDUSTRY (CHEMICAL ENGINEERING GROUP) (at the Waldorf Hotel, Aldwych, London, W.C.2), at 12.15 p.m.—Twenty-fifth Annual General Meeting.

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir Richard Winn Livingstone: "Education, To-day and To-morrow", 9: "Adult Education".

INSTITUTION OF ELECTRICAL ENGINEERS (TRANSMISSION SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. J. L. Carr: "Remote Switching by Superimposed Currents".

Wednesday, May 10—Thursday, May 11

INSTITUTION OF NAVAL ARCHITECTS (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 2.30 each day.—Boiler Symposium on the Application of Water-Tube Boilers to Merchant Ships.

Thursday, May 11

IRON AND STEEL INSTITUTE (at 4 Grosvenor Gardens, London, S.W.1), at 10.45 a.m.—Annual General Meeting.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Annual General Meeting. Mr. R. J. Halsey: "Modern Submarine Cable Telephony and the Use of Submerged Repeaters".

INSTITUTION OF ELECTRICAL ENGINEERS (CAMBRIDGE AND DISTRICT WIRELESS GROUP) (at the University Engineering Department, Trumpington Street, Cambridge), at 8.15 p.m.—Dr. E. B. Moullin: "The Contribution of Cambridge to Radio Engineering".

Friday, May 12

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. G. L. Camm: "An Analysis of the Motion of Cepheid Variable Stars, with reference to Galactic Rotation and Absorption"; Mr. E. H. Linfoot: "The Schmidt-Cassegrain Systems and their Application to Astronomical Photography".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Dr. W. T. Astbury, F.R.S.: "Fibres and Fabrics, Old and New—Their Chemical Structure and Physical Properties".

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Exhibition of Technical Films.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DISTRICT ENGINEER by the Ceylon Government Railway—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.926A) (May 10).

SENIOR POST under the AERONAUTICAL INSPECTION DIRECTORATE (applicants should possess a first-class Honours Degree in Physics or a recognized equivalent, have had industrial radiological experience, be conversant with the various modifications of the technique of X-ray crystal analysis, and be capable of carrying out independent *ad hoc* scientific investigations in electro-physics)—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. A.499A) (May 10).

LECTURER (man or woman) IN GEOGRAPHY AND MATHEMATICS—The Principal, Dudley and Staffordshire Technical College, Dudley (May 12).

LECTURER IN PRODUCTION ENGINEERING at the Coventry Technical College—The Director of Education, Education Offices, Coventry (May 12).

LECTURE-ASSISTANT IN MATHEMATICS—The Registrar, The University, Manchester (May 13).

GRADUATE ASSISTANTS IN MECHANICAL ENGINEERING, ELECTRICAL ENGINEERING, and GRADUATE (or equivalent qualification) in BUILDING AND STRUCTURAL ENGINEERING, at the Darlington Technical College and Technical School—The Chief Education Officer, Education Office, Darlington (May 15).

SPEECH THERAPIST (female, full-time)—The Director of Education, Huntriss Row, Scarborough (May 15).

LECTURER IN MATHEMATICS—The Principal, Kingston Technical College, Kingston, Surrey (May 15).

ASSISTANT LECTURER IN SCIENCE—The Principal, Domestic Science College, Knighton Fields, Leicester (May 17).

ASSISTANT CIVIL ENGINEERS (temporary) on the Staff of the Ministry of Home Affairs, Government of Northern Ireland—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.940A) (May 17).

ASSISTANT CIVIL ENGINEER (temporary) on the Staff of the Ministry of Finance, Government of Northern Ireland—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.941A) (May 17).

DEPUTY ELECTRICAL ENGINEER AND MANAGER (temporary) or CHIEF ASSISTANT ELECTRICAL ENGINEER (temporary) (location, City of Chester)—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.807XA) (May 17).

CHEMISTS for service with Petroleum Company in the Middle East—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.1843X) (May 17).

TWO DEMONSTRATORS IN PHYSIOLOGY (one for BIOCHEMISTRY)—The Secretary, King's College, Strand, London, W.C.2 (May 18).

ASSISTANT TECHNICAL OFFICER—The Executive Officer, Essex War Agricultural Executive Committee, Essex Institute of Agriculture, Writtle, Chelmsford (May 20).

LECTURER IN THE DEPARTMENT OF MATHEMATICS—The Registrar, University College, Singleton Park, Swansea (May 20).

DRAINAGE AND IRRIGATION ENGINEER by the Gambia Government—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E. 950 A) (May 24).

LECTURER in charge of the DEPARTMENT OF BOTANY—The Registrar, University College, Leicester (May 27).

DIRECTOR OF THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

DEPUTY ENGINEER of the Sheffield Waterworks Undertaking—The General Manager and Engineer, Waterworks Office, Town Hall, Sheffield 1 (May 31).

CHAIRS OF PHILOSOPHY, ZOOLOGY and COMPARATIVE ANATOMY—The Registrar, University College, Cathays Park, Cardiff (May 31).

CHAIR OF BOTANY—The Registrar, The University, Sheffield (June 1).

CHAIR OF NATURAL PHILOSOPHY, United College, St. Andrews—The Secretary, The University, St. Andrews (June 15).

CHIEF ENGINEER AND GENERAL MANAGER of the Gloucester Electricity Undertaking—The Town Clerk, Guildhall, Gloucester.

ASSISTANT LECTURER IN SOCIAL PHILOSOPHY to assist in the teaching of the elements of Ethics and Social Philosophy, and an ASSISTANT LECTURER IN GEOGRAPHY to assist with the teaching of Geography—The Acting Secretary, London School of Economics, The Hostel, Peterhouse, Cambridge.

SCIENCE AND MATHEMATICS MASTER, for English High School for Boys, Istanbul—The British Council, 3 Hanover Street, London, W.1 (endorsed "Istanbul").

ASSISTANT LECTURER (Grade III) IN THE DEPARTMENT OF INORGANIC AND PHYSICAL CHEMISTRY—The Registrar, The University, Liverpool.

ASSISTANT MASTER FOR ENGINEERING SUBJECTS in the Burton-upon-Trent Technical Institute and Junior Technical School—The Secretary and Director of Education, Education Offices, Guild Street, Burton-upon-Trent.

DIRECTOR OF THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION—The Chairman of the Council, B.E.A.I.R.A., 15 Savoy Street, Strand, London, W.C.2.

RESEARCH ASSISTANT (BIOLOGY and/or PHYSICS) for Hospital Laboratory—The General Superintendent, Christie Hospital and Holt Radium Institute, Withington, Manchester 20.

INTERNATIONAL CO-OPERATION IN TELECOMMUNICATIONS

THE machinery of international co-operation, which has been allowed, in the political sphere, to break down from frictional wear and tear, is being hopefully re-examined as a prelude to reconditioning or reconstruction. Chatham House has been happily inspired to inaugurate a series of monographs on international transport and communications, and the series opened appropriately with the discussion of international telecommunications*: appropriately, because the Union to which was first entrusted in 1865 the organization and regulation of telecommunications was, as the author of the monograph justly says, "One of the earliest, and also one of the most successful organs of international collaboration". The structure, which was founded on the International Telegraph Union, grew large and somewhat sprawling with the rapid expansion, first of line telephony, and later of radio communication systems. It was redesigned and given good architectural form at a conference held in Madrid in 1932. There the International Telecommunication Union was created as the supreme organ of collaboration in these fields. Brigadier-General Sir Osborne Mance's book is an admirable guide to the past history of international telecommunications, and to those considerations which will be important in the planning and management of their future.

It has been remarked, by those who have had the privilege of participating in the international conferences on telecommunications and on meteorology, that in general the technical world has managed these partial Leagues of Nations more successfully and fruitfully than did the political world its more ambitious and naturally less tractable League. These successes were in part due to the simple and inescapable conviction that the choice lay only between collaboration and chaos. But that has been demonstrated to be true also in the political sphere. There is justification for the claim that the community of interest and mode of thought engendered by a common technique was a major factor in the success attained. The secure foundation of the common technique was, in turn, that universal freedom of interchange of scientific knowledge and thought which has been an enduring encouragement to all who believe that man can learn to forget frontiers without forgetting national pride.

The problems of line communication are of great technical interest, but they are technically, organizationally and politically of a pristine simplicity when compared with those of radio communication. Mutual interference through common use of a medium which facilitates the passage of intelligence to world-wide distances, at an expenditure of power which may be less than that of a pocket torch, can only be avoided by skilled adherence to stringent regulations. The difference in the area served by radio communications on different wave-lengths, the variability of the

* International Telecommunications. By Brig.-General Sir Osborne Mance. (Issued under the auspices of the Royal Institute of International Affairs.) Pp. xii+90. (London, New York and Toronto: Oxford University Press, 1943.) 7s. 6d. net.

area with the time of day and with the season, the limitation of the service by noises of natural origin —mainly radiated from lightning flashes—all these and similar factors lead to keen competition for wave-length channels, which must be allocated internationally if radio peace is to be maintained.

It has been suggested that allocation should be based on two principles which seem unanswerable in the abstract, but which have not yet been accepted as a basis of action. The first principle is, in its broadest form, that first claim should be conceded to those services in which a metallic conductor cannot be used to link sending to receiving station. Thus maritime and aircraft services would be given absolute priority; and the use of line telegraphy and telephony would be encouraged, in preference to radio links, wherever they could assure a service. The second principle is that where services with a legitimate claim (within the first principle) to radio allocations come into competition for channels, preference should be given to the one which is of the highest social importance. In the absence of an agreed set of principles such as these, allocation has remained a matter for bargaining, compromise and successive readjustments. Difficult as would be the working out of the ethical, organizational and political problems implicit in the "highest social importance" criterion, the absence of even this golden foot-rule leaves still greater difficulties to be faced. Prestige, propaganda and profits are noisier claimants than principles.

The maritime services demand not merely straightforward communication of the content of the spoken or the written word, not merely that vital aid to determination of longitude provided by time signals, the value of which depends on the infinitesimal time they lose in travelling halfway round the world. They require, too, those radio aids to navigation which depend on the fact that it is not difficult to measure, at a receiving station on ship or shore, the bearing, relative to true north or to the ship's heading, from which signals of known place of origin are coming in. Radio beacons and direction-finding services require a special place in the most-favoured-service category.

Still more exacting are the claims of air transport. Radio, with its lusty infant progeny of 'radar' devices, offers the air line of the immediate post-war future a complex of communication, navigational and safety services which leave only one major hazard in all-weather flying. But such services demand monopoly use of a considerable range of wave-lengths, denied to any other user within a wide area which may, in some cases, be a world area.

These are the services which would stand indisputably at the top of the priority list based on the first general principle; the broadcasting services would certainly claim first place in the "social importance" scale—even though the cynic will suggest that a mad dog may, while he runs free, be of more immediate social importance than a young Pasteur.

It is not too soon for the United Nations to be considering now a sound double framework of basic principles and technical performance in the broad field of international communications. Within such a framework must be fitted the post-war solutions of problems which will have become more numerous and more pressing with war-time progress in radio and with the demands of rehabilitation. It may well be believed—and hoped—that no such opportunity for rationalization and reconciliation of competing claims in the field of international communications will ever again present itself.

NATURE CONSERVATION AND ECOLOGY

In his recent broadcast address, the Prime Minister rebuked those "comfortable people who . . . would rather postpone building homes for the returning troops until they have planned out every acre in the country to make sure the landscape is not spoiled". It is not, perhaps, immediately clear who are the people thus referred to, but we can be sure that the scientific advocates of nature conservation are not among them. They, at any rate, will be content if the place allotted to them in the scramble for post-war priorities is not too near the end of the queue. This is made clear in an admirable pamphlet recently published by the British Ecological Society*, in which the human or social background is constantly kept in view.

When the Nature Reserves Investigation Committee was appointed in response to an official request in 1942, a committee of the Ecological Society was already engaged in considering the same subject and was able to assist in the inquiries. When the first-named Committee's report was published (see NATURE, June 26, 1943) the work of the Ecological Committee might have been thought to require no further record. It was considered, however, that the distinctively ecological point of view deserved to be independently formulated, and the report now published is designed to do this. It forms a very valuable supplement to the earlier report, and its extended treatment of the subject may be found more attractive by many readers.

Ecologists are, of course, primarily concerned with the scientific (or research) and educational aspects of nature conservation, though it is emphasized that these only rarely conflict with, and often reinforce, the claims of amenity and recreation. The subjects of ecological study are less the individual species than the interdependent aggregations or 'communities' of animals and plants that occur in Nature, and ecologists are specially desirous of preserving these communities. "Oak, beech and ash trees, heather and bilberry and bog-moss are very unlikely to disappear altogether from the country, but their continued existence as species is of very limited use to the ecologist if all the oakwoods, beechwoods and ashwoods, the heather and bilberry moors and the undrained *Sphagnum* bogs are destroyed or so modified that they no longer

* "Nature Conservation and Nature Reserves". Report drawn up by a Committee and approved by the Council of the British Ecological Society. Pp. 38. October 1943. (Cambridge University Press.) 1s. 6d.

represent natural plant communities." For this reason the ecologists regard with some suspicion the term 'species reserves' given by the Nature Reserves Investigation Committee to the category of reserves intended to secure the survival of rare or very local species. In every case it is the habitat rather than the individual species to which the conservators must direct their efforts, and 'species reserves' are simply 'habitat reserves' differing from others in the same category only in the reasons for their selection.

The ecologists distinguish between 'natural' and 'semi-natural' communities of plants, with their associated animals, and point out that efforts at conservation should embrace the latter as well as the former. For example, in the southern parts of the British Isles, hedgerows and small copses provide the main habitat for many species of wild flowers and nesting sites for perhaps the majority of our smaller birds. Their destruction, advocated and perhaps inevitable in the interests of large-scale mechanized farming, would not only destroy much of the charm of the lowland countryside but also might have indirect effects harmful in the long run to agriculture, such as the elimination of insectivorous birds and even the erosion of the lighter soils by wind or water.

It may perhaps be doubted whether the distinction drawn by the ecologists between 'natural' and 'semi-natural' communities is of much practical significance in Great Britain. Communities which are 'natural', in the sense that they owe none of their features to the effects of human activities, are probably very rare and are to be looked for only on the tops of the highest mountains and the wilder parts of the sea-coast. Further, the distinction is not always consistently adhered to even in the Ecological Committee's report itself. Thus, on p. 8, the rough grazings of hill pastures "which have never been ploughed or manured" are stated to consist of "entirely wild vegetation", while on p. 4 it is stated that "most of the grassland of these hill grazings owes its present condition largely to the continual nibbling of sheep". It may be added that land which is constantly grazed can scarcely be described as never having been manured.

That part of the report which deals with the relation of nature conservation to the activities of the Forestry Commission is of particular interest. In view of the urgent national need for coniferous timber, it is inevitable that the chief attention of the Commission must be devoted to supplying this. Coniferous plantations are admittedly not picturesque, and their associated fauna and flora are impoverished and lacking in interest to the ecologist, although "the plantations will lose much of their repellent uniformity and ecological poverty as they grow older". The report notes with satisfaction, however, that the Commission has not lost sight of more remote interests, as, for example, in setting aside as 'permanent forest reserves' certain areas of old, undisturbed, deciduous woodland, and it suggests that the Commission might be given a broader mandate to enable it to deal with questions at present excluded from its scope.

The Ecological Committee takes a similarly realistic view of the relations which should obtain between nature conservation and agriculture and game preserving. In connexion with the last-named subject, the Committee rightly deprecates attempts to introduce exotic species of animals. Its condemnation might have been more emphatic. In the past, such introductions have been mostly due to the whims of individual landowners; but it is a regrettable fact that even to-day one does occasionally meet people whose idea of a nature reserve seems to be a combination of Whipsnade with the less formal parts of Kew Gardens.

As regards the administrative machinery which it would like to see set up for the establishment and supervision of nature reserves, the Committee of the British Ecological Society cordially endorses most of the recommendations of the Nature Reserves Investigation Committee. While the latter, however, looks forward to the institution of a national nature reserves authority under the Ministry of Town and Country Planning, the Ecological Committee would like to see a national wild-life service with a status similar to that of the Medical Research Council, under the Privy Council, to embrace the whole field of the native fauna and flora of Great Britain. To this, presumably, would have to be added the conservation of geological sites advocated by the Nature Reserves Investigation Committee. Doubtless we may have to wait a long time to see the full development of such large-scale plans, but meanwhile there is much that might be done to educate the general public in the meaning and methods of nature conservation. For this purpose the pamphlet issued by the British Ecological Society deserves a wide circulation.

WHALEBONE WHALES IN THE ANTARCTIC

The Southern Stocks of Whalebone Whales

By Dr. N. A. Mackintosh. (Discovery Reports. Issued by the Discovery Committee, Colonial Office, London, on behalf of the Government of the Dependencies of the Falkland Islands.) Pp. 197–300. (Cambridge: At the University Press, 1942.) 15*s*. net.

THE main object of the research conducted by the "Discovery" Committee is the investigation of the biology of the economically valuable whales frequenting Antarctic waters. A number of "Discovery" reports dealing with various aspects of the subject have already been published, and Dr. Mackintosh's present paper incorporates much of this material in a comprehensive survey of pre-war conditions. At the present time, whaling is at a standstill, and the stock of whales is enjoying a respite from pursuit likely to extend to the end of the War. The effect of this war-time period of protection can only be measured comparatively in terms of conditions prevailing when whaling ceased. From this aspect, Dr. Mackintosh's review is of particular value. It should be emphasized that his memoir is by no means merely a compilation of already published data. It contains a great body of additional informa-

tion which the author has analysed, and also uses statistics of the whaling industry to provide a statement on the condition of the southern whale stocks which will be invaluable in the investigations necessary when whaling becomes active again.

The specific identity of the main constituents of the Antarctic catch—blue, fin and humpback whales—is briefly considered. This is followed by a section of more general interest in which weights of large whales are stated and formulæ for assessing weight from linear dimensions examined.

The remarkable exclusiveness of krill (*Euphausia superba*) as the food of all the whalebone whales while in the Antarctic has been proved by examination of many thousands of stomach contents. The record of any organism other than krill is so infrequent that its presence can be attributed entirely to chance; and the deterioration in the condition of whales which have moved to warmer waters where this crustacean is not available gives further proof of its importance in the cetacean diet.

The parasites infecting whales, particularly the ecto-parasites, are interesting not only from the range of forms which occurs—Diatomacea, Protozoa, Amphipoda, Copepoda and Cirripedia all figure in the list—but also because of the indications some of them give of migratory movements. Only whales which have been a long time in cold water carry a heavy film of diatoms; on the other hand, the copepod Pennella, a parasite in warmer water, indicates by its actual or recent presence in whales killed in the Antarctic that the cetaceans had not long migrated from lower latitudes.

Figures for the mean length at which sexual maturity is attained have been confirmed or made more definitely known. From this information, obtained by careful examination of genitalia and accurate body-length measurement, it has been possible to compute the proportion of mature and immature whales in the commercial catch, given only species, sex and length of the animals involved. The old corpora lutea in the ovaries, which are persistent, it may be throughout the life of the animal, have helped to provide a solution for many of the problems associated with the sexual cycle. Although much has still to be done, it is clear that the advance in knowledge of this aspect of the work has been most satisfactory.

The statistics of the whaling catch are considered in some detail. An idea of the scope of the industry is gained from the number of whales killed at southern whaling centres between 1904 and 1939. It is 636,426. Although the catches at tropical and sub-tropical stations are included in this total, the preponderating importance of the operations in the Antarctic, including South Georgia, is shown by the fact that 509,784 whales, or more than 80 per cent of the total, were slaughtered in those regions. In the last prewar season alone 35,770 whalebone whales were taken in the Antarctic.

Marking of whales and the subsequent recovery of the darts from harpooned animals serves a dual purpose. The first and obvious one is the information about migration which can be obtained from recovered darts, and one of the most important new contributions in the paper is concerned with the difference between the humpback and the large rorquals in migration behaviour. During the Antarctic summer, the humpbacks are not distributed uniformly in the far south but are grouped in clearly defined communities, the position of which, Dr. Mackintosh has shown, can be correlated with winter haunts of this species on the South American, African, West Australian and New Zealand coasts. The evidence of marking indicates that each group of humpbacks keeps to its own approximately north–south migration route and that there is little intermixing of adjacent communities. The migrations of the blue and fin whales are less well defined. In winter they disperse in the warmer waters of the southern hemisphere to a greater extent than the humpbacks, and although in the southern summer they have a tendency to concentrate in the same areas as the humpbacks and to return to the same part of the Antarctic after their northward migration, unlike the humpback they sometimes move from one area to another.

But in addition to its primary intention, whale marking can also be used to give an indication of the proportions in which the species distinguished may be considered to be represented in the areas covered. The species ratio of whales marked is blue 13 per cent, fin 76·3 per cent, humpback 10·7 per cent. These percentages bear a remarkable similarity to the species ratio of whales observed at sea by the "Discovery" Committee's vessels, namely, blue 16·5 per cent, fin 77·1 per cent and humpback 6·4 per cent. The percentage of blue, fin and humpback whales killed in the Antarctic in the 1933–38 period was 44, 41 and 14 per cent respectively, figures which point to a disproportionately intensive attack on the population of blue and humpback whales. That the stock of these two whales is being depleted is shown by the progressive decline in the percentage of the two species in the annual catch, by the reduced size and age of the whales killed, and particularly in the humpback by its virtual disappearance in areas where formerly it was abundant. Consideration of this problem is made difficult by a number of qualifying factors, such as the development in the efficiency of hunting methods, regulations protecting certain classes of whales, weather conditions, area exploited, relative economic value of different species and so on.

The report contains much that is of interest to the general biologist, but for those whose concern is the conservation of the stock of whales in the south it must be an indispensable work of reference.

F. C. FRASER.

STATISTICS OF LITERARY VOCABULARY

The Statistical Study of Literary Vocabulary
By G. Udny Yule. Pp. ix+306. (Cambridge: At the University Press, 1944.) 25*s*. net.

A NEW book by Mr. Udny Yule is a statistical event which, though of great rarity, is all the more welcome when it occurs. This, however, is not a formal treatment of a subject which has already shaken down into definite lines of development, or even a systematic introduction to such a subject. Rather is it an account in volume form of Mr. Yule's incursion into a novel and interesting field of research.

That authors have their idiosyncrasies in the choice and use of words has been recognized by literary critics from the earliest times; but attention in the past has been mainly directed to the peculiar or unusual words, or at best to qualities of verbal

style which are so obvious as to require no labour to establish their existence, such as the Germanic vocabulary in Carlyle's work or the Anglo-Saxon preferences of William Morris. Studies of these matters, useful as they are, did not tell Mr. Yule what he really wanted to know about an author's vocabulary. The statistician is interested in populations even of the most ordinary things, and what Mr. Yule wished to discover was what the vocabulary was like *as a whole*. "To tell me that there is a small mole on Miranda's cheek may help me to identify the lady, and may in conceivable circumstances be quite useful information to the police, but it hardly amounts to a description of her alluring features." Mr. Yule might have added that identification by individual feature is a dangerous procedure in literature. Shakespeare's use of legal words and phrases has been claimed as a favourable argument for the Baconian heresy, and the use of conventional adjectives of colour in the Iliad has been supposed to confirm the legend that Homer was blind.

Mr. Yule, then, embarks on the task of forming a picture of a writer's whole vocabulary. He has concentrated his work on nouns, as being most likely to be characteristic, and has drawn his material from five main sources—the Bible, the works of Thomas à Kempis, those of a rival claimant to the authorship of the "Imitatio Christi", Gerson, the essays of Macaulay and the works of John Bunyan. Even though help could be obtained from a concordance in some cases, this involved a fairly extensive inquiry by sample. There is an interesting account of the technique used to obtain really representative samples from the heterogeneous material available. Mr. Yule finally decided on what he calls "spread" sampling, a sort of stratification which distributes the sampling uniformly over the population.

The frequency-distributions of nouns so obtained have interesting features in common. The majority of nouns—about half the vocabulary—occur only once, fewer occur twice, fewer still thrice and so on, the distribution being J-shaped with a long tail furnished by a few words occurring very frequently, such as *Deus* in the "Imitatio" and *King* in Macaulay's essay on Hampden. Mr. Yule recognizes that perhaps for larger samples the modal frequency might be at two or three occurrences and tests the possibility with typical ingenuity, not by extending his already extensive samples but by applying himself to a document in which the writer's vocabulary is severely limited, the Gospel of St. John in Basic English; even here he finds the highest proportion of nouns, about 25 per cent, occurring only once.

The *litterateur* who resents having the cold light of science turned on inspired passages from the classics in this way may stop here and ask whether all this counting and measuring tells him anything he did not already know. If he is prepared to learn, there is in fact a good deal of benefit he can derive from the exact type of study exemplified in Mr. Yule's work. A single by-product of the frequency-distributions will suffice to exemplify their suggestive character. Suppose a reader with no previous knowledge of Latin, and wishing to study medieval authors in the original, decides to begin with the "Imitatio Christi"—an excellent choice because of its simple style. Suppose a noun has to occur a dozen times before its meaning is firmly stamped on his memory. Then at the end of a first reading he will remember 140 out of 1,168 nouns occurring in the book, only about one eighth of the vocabulary encountered.

There are several peculiar features of the word-distributions, one of which is that they change their form as the size of sample increases because of the appearance of new words. Mr. Yule devises a characteristic of the distribution which is independent of the size of sample and permits of comparison between different authors. The work is closely related to the theory of accident distributions. If the author's store of words is regarded as a population with varying proneness to occurrence, the observed distribution may be considered as a compound Poisson. There is one important difference from accident statistics as usually available, because we do not know the number of words at risk which have 'escaped accident', that is to say, have not occurred. But this difficulty is successfully surmounted; and if our carping critic dismisses as absurd the idea that an author selects words out of his store like a man taking tickets at random out of a hat, he has still to explain the fact that Yule's characteristic *is* practically independent of sample size in all the examples he discusses.

In a chapter on "Sources of Fallacy", Mr. Yule does much to clarify the problems with which he is faced and incidentally exhibits serious shortcomings in the work of some of his predecessors. He then turns to a discussion of the English vocabularies of Macaulay and Bunyan. The chance observation that the proportions of nouns classified by initial letters differed very considerably between the two led him to a study of etymological differences. It appears that there is a higher proportion of Romance words in Macaulay which reflects itself in the alphabetical distribution.

Finally, Mr. Yule comes to the question which originally led him to the whole inquiry, whether there is anything in the vocabularies of the acknowledged works of à Kempis and Gerson which throws light on rival claims of the two men to authorship of the "Imitatio". He concludes, after a thorough examination, that Gerson is a most unlikely candidate, whereas Thomas could quite well have been the author. This confirms the evidence provided by distributions of sentence lengths. To me the evidence against Gerson appears quite decisive.

Readers who are unfamiliar with statistical methods need not be deterred from studying this book. Mr. Yule allows himself whatever technique he requires to solve his problems; but, in fact, that technique is not very elaborate and is accompanied by simple explanations which will smooth the way for anyone who is not afraid of an occasional algebraic symbol. The whole work exhibits all those qualities which have made its author celebrated among his fellows. There is the same accuracy of detail, the same careful examination of all the pitfalls, the same cautious but steady advance into unknown territory, the same flashes of insight, the same experimental testing of every link in the chain of reasoning, the same care to make the author's meaning quite clear.

To statisticians the book will be of interest not merely because it throws up all sorts of problems for their consideration, but also as an account of a model investigation in a new and difficult field. To anyone, statistician or not, who takes an interest in the languages which he learns and uses, the book will present many new points of view on a fascinating subject, and much definite information about matters which have hitherto been studied in a vague and intuitive way. M. G. Kendall.

THE AFFINE CONNEXION IN PHYSICAL FIELD THEORIES

By PROF. E. SCHROEDINGER
Dublin Institute for Advanced Studies

1. The loss of connexion by general invariance. The essential physical entities are mathematically described as *invariants, vectors, tensors*. That comes from the isotropy and homogeneity of space in Euclidean geometry—or from the pseudo-isotropy of space-time, in the Restricted Theory of Relativity. When the latter is replaced by the idea of *general* invariance, that is, by regarding the three space-co-ordinates and the time only as continuous labels of the world points, which labels may equivalently be replaced by any quadruplet of continuous functions of themselves, the notion of vector or tensor subsists, but any such entity is now necessarily bound to a given world-point, it is 'a tensor at P'. For example, the *displacement*-vector, dx_k, leading from a world-point P with co-ordinates x_k (that is, x_1, x_2, x_3, x_4) to a neighbouring point Q with co-ordinates $x_k + dx_k$, is the prototype of a contravariant vector A^k at P. If you change the labels (that is to say, if you execute a general transformation of the frame) the A^k transform *by definition* as the dx_k, thus* :

$$d\hat{x}_k = \frac{\partial \hat{x}_k}{\partial x_l}\, dx_l \text{ and } \hat{A}^k = \frac{\partial \hat{x}_k}{\partial x_l}\, A^l. \qquad (1)$$

This rule is obviously inherent in the world point P, because the partial derivatives which form the coefficients *vary* from point to point. In consequence of this, you cannot directly compare a 'vector at P' with a similar 'vector at Q', even when Q is an infinitely neighbouring point.

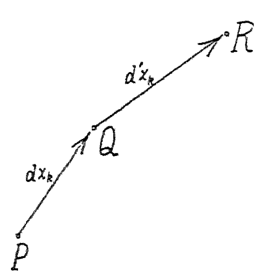

FIG. 1.

For example (see Fig. 1), on proceeding first from P to Q by dx_k, then from Q to R by $d'x_k$, you cannot tell whether the second step is *equal* in direction and length to the first one or not. The bare notion of continuity tells you, of course, that, to indicate *equality*, the $d'x_k$ have to be *very nearly* the same as the dx_k, they must not differ by more than second-order quantities. But within this margin there is no distinction. You cannot tell whether you are moving along a straight line or along a circle, whether in uniform, retarded or accelerated steps. *You have lost the connexion between neighbouring points.* You could no longer, or only in a very restricted way†, set up differential equations to control geometrical or physical *fields*.

* The sum from 1 to 4 always to be taken for an index occurring twice in the same term (as the l in (1)).

† Certain derivatives and combinations of derivatives (H. Weyl[2] calls them "linear fields") do retain a meaning even in a non-connected manifold; for example, the *gradient* of a scalar or the *curl* of a covariant vector.

2. General affine connexion. To recover this possibility you must reinstate a *connexion*. You must reintroduce some principle to replace the trivial principle of Euclidean geometry: two vectors are equal when their components are equal, quite irrespective of their association with points of the manifold.

What you want to know, or rather, what you want to 'state by decree' in an invariant manner, is *which* vector at the neighbouring point Q $(x_k + dx_k)$ is to be considered the *same* as a given vector A^k at $P(x_k)$.

The components of that "vector at Q" must differ but infinitesimally from the A^k, and so we suitably term them $A^k + \delta A^k$. The simplest and most straightforward, and at the same time a fairly general way of making the required 'decree', is to demand that the δA^k shall be some bilinear functions of the dx_k and of the A^k, thus :

$$\delta A^k = -\,\Gamma_{ml}{}^k\, A^m dx_l, \qquad (2)$$

the $\Gamma_{ml}{}^k$ being 64 coefficients, which can vary arbitrarily from world-point to world-point, that is, they are arbitrary continuous functions of the x_k (the minus sign in (2) is conventional).

If we adopt (2) without any further restrictions on the Γ's, we say we impose (the most general form of) an *affine connexion* or an 'affinity' on our continuum. The Γ's are called the components of the affine connexion. Formula (2) is said to determine 'parallel displacement' according to this affine connexion. This name is objectionable in both its terms. The Euclidean analogue is not 'parallelism' but 'sameness'; moreover, the word 'displacement', used before for the little vector with components dx_k itself, now indicates the act of transferring the vector A^m along dx_l. For clearness and brevity, I shall refer to the parallel displacement just as 'the transfer'.

Equation (2) and the notions introduced with regard to it are common to all (generally invariant) field theories. But various theories differ widely as to the way in which the affine connexion is introduced (see Sect. 4 and 5 below).

3. Curvature. Common to all theories is also the basic notion of *curvature*, which results from the affine connexion as follows. The notion of 'sameness', referring to neighbouring points, can *not* in general be extended, by continuous transfer along a curve, to world points finitely apart from one another. The transfer of a vector A^k from P to the distant point Q along a given curve C *is*, of course, unique and reversible; that is, on transferring back along the *same* curve you get back the initial vector at P. But the transfer along some other curve C' would lead to another vector at Q. Alternatively, if you transfer A^k from P to Q along C, then back to P along C', you obtain at P a vector different *in direction and length* from the original A^k.

In the complicated case under consideration (*four* dimensions; *general* affinity) it is scarcely possible to grasp intuitively this interesting behaviour, which is attributed to the *curvature* the continuum possesses in virtue of the affine connexion we have impressed on it.

Mathematically, the curvature is described by a fairly complicated entity, the Riemann-Christoffel curvature tensor $B^i{}_{k,lm}$, which is *always* antisymmetric in l, m, but has in general no other symmetry properties. It has therefore, in the general case, $4 \times 4 \times 6 = 96$ independent components. It is generally believed that this tensor is fundamental in

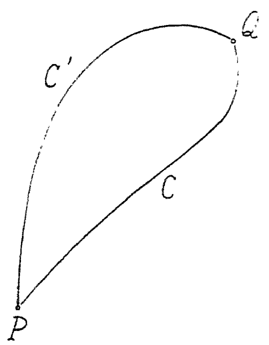

FIG. 2.

field-theory, but that it enters only in the form of its 'contractions', of which there are, in general, two*, namely, $B^m{}_{k.lm}$ and $B^k{}_{k,lm}$. We shall have to speak of them later.

4. The affinity resulting from Riemannian metric. Now let us turn to the widely different manners in which various theories introduce the affine connexion $\Gamma_{ml}{}^k$.

Einstein's[1] theory of gravitation is based on Riemannian metric, and the affine connexion results from the metric as a secondary item thus. By introducing the invariant line-element

$$ds^2 = g_{ik}\, dx_i\, dx_k, \tag{3}$$

you associate with *any* contravariant vector A^k its *invariant*

$$g_{ik}\, A^i A^k \tag{4}$$

('square of the length'). The required *correspondence* between the vectors A^k at P and $A'^k(= A^k + \delta A^k)$ at the neighbouring point Q can then be set up by adopting the following *four* rules :

(i) The invariants (4) of corresponding vectors shall be equal.

(ii) If A' and B' correspond to A and B respectively, then $A' + \lambda B'$ (where λ is any numerical constant) shall correspond to $A + \lambda B$.

(iii) The δA^k shall be linear functions of the dx_l.

The adoption of these three rules entails the general form (2) for the δA^k. We add a fourth :

(iv) The $\Gamma_{ml}{}^k$ shall be symmetric in m and l, that is, it shall equal $\Gamma_{lm}{}^k$.

The Γ's which result from these four assumptions are the so-called Christoffel-brackets, $\left\{ {k \atop lm} \right\}$, functions of the g_{ik} and their first derivatives, linear in the latter. We do not need their explicit expressions here.

5. Weyl's Theory and Eddington's point of view. H. Weyl[2] in his famous theory of 1918, the first to account for gravitation *and* electromagnetism, dropped the *first* of the above postulates and replaced it by the following :

(i') The invariants of corresponding vectors shall bear a constant ratio to one another, depending only on the two points P and Q. (Of course, this 'gauging ratio' can differ only infinitesimally from unity.)

The underlying idea was that one ought not to admit the physical possibility of comparing 'lengths' at distant world points, as Einstein's theory did indeed admit. Weyl's modification automatically introduces, in addition to the 'metrical tensor' g_{ik}, a 'metrical vector' φ_k of equally fundamental standing with g_{ik}, and capable of being interpreted as the electromagnetic potential. For the Γ's you now no longer get just the $\left\{ {k \atop ml} \right\}$, but

$$\Gamma_{ml}{}^k = \left\{ {k \atop ml} \right\} - \tfrac{1}{2} g_{ml}\, \varphi^k + \tfrac{1}{2}\delta_m{}^k \varphi_l + \tfrac{1}{2}\delta_l{}^k \varphi_m. \tag{5}$$

Sir Arthur Eddington[3], in what he modestly termed a generalization of Weyl's theory, was actually the first to take an entirely different attitude of great significance for the progress of the subject. The general affine connexion (2) is adopted *immediately* (only with the symmetry restriction $\Gamma_{ml}{}^k = \Gamma_{lm}{}^k$, which reduces the number of Γ's from 64 to 40). *Metric is made a secondary item.* To appreciate the superiority of this attitude we observe the following.

6. The restrictive Hamiltonian principle. A connected manifold of any type is not yet a field theory. To make it that, you have to impose on its basic geometrical field-quantities—the g_{ik} or the g_{ik} and φ_k or the $\Gamma_{ml}{}^k$, as the case may be—certain restrictions, differential equations. One wishes them to flow from some general principle which leaves as little arbitrariness as possible. Now almost every kind of restriction contemplated hitherto has turned out to be equivalent to a *Hamiltonian principle*, demanding that the space-time integral of an invariant density $\mathfrak{L}$, taken over any fixed region, be *stationary* :

$$\delta \int \mathfrak{L}\, dx_1\, dx_2\, dx_3\, dx_4 = 0. \tag{6}$$

This very convenient way of searching for the 'right' field-equations (you just have to search for 'the right $\mathfrak{L}$') has been widely adopted, and there are general reasons for believing that it is justified. (*If the field equations amount to a Hamiltonian principle, the conservation laws are an automatic consequence of the general invariance.*)

7. The superiority of the affine point of view. Now if our manifold carries an affine connexion, but *no* metric, the requirement that $\mathfrak{L}$ be an *invariant density* narrows the choice considerably. For the only simple *tensors* indicated by the affinity are in this case the Riemann-Christoffel tensor $B^i{}_{k,lm}$ and its contractions, mentioned before. The latter are *covariant tensors of the 2nd rank*. They cannot be contracted a second time to form an invariant, because we have no metric and thus no means of raising and lowering indices. If we exclude the B-tensor itself as 'too complicated', then to get an *invariant density* there seems to be no other means but to avail oneself of the fortunate fact that the square-root of the determinant of any covariant 2nd rank tensor *is* one.

On the other hand, if the basic geometrical field-quantities include a metrical tensor g_{ik}, you can raise and lower indices to your heart's desire and you can turn every *invariant* into a *density* by multiplying it by $\sqrt{-g}$—in a word, the choice for $\mathfrak{L}$ is then well-nigh unlimited.

Eddington[3] was the first to point to the somewhat unique possibility of taking for $\mathfrak{L}$ the square-root of the determinant of the 2nd rank curvature tensor. Einstein[4], early in 1923, worked it out more fully. Both of them were ultimately inclined to think that it led to a discouraging dilemma. You were either confronted with a serious quantitative contradiction

* See the first footnote to Sect. 1. Contraction is only admissible between one upper and one lower index.

of facts, or you had to modify the original simple idea to such an extent that the multitude of possibilities for £, expelled by the front-gate, crept in by the back-door, and rendered the whole enterprise extremely unsatisfactory.

Recent attempts in the same direction take a less pessimistic view. But before speaking of them, we must supplement the "general picture of a field theory" at one point.

8. The problem of identification. When a system of geometrical field-equations has tentatively been established in the way sketched above, the field components which they connect (which are either the original basic geometrical field-quantities or, more often, vectors and tensors built up from them) have to be *identified*, one by one, with the components of the known physical vectors and tensors, connected by more or less well-known *physical* field equations. Now, this business of identification is not so unambiguous and trivial as might be believed on considering that, after all, *gravitation* must be described by a symmetrical g_{ik}-tensor with 10 components, *electromagnetism* by an antisymmetric tensor (6-vector), governed by Einstein's and Maxwell's equations respectively. That does not seem to leave much opportunity for making mistakes in associating geometrical and physical entities.

But even so, the allotment of roles to the single components must be carefully considered. Physicists have got the habit of associating the *electric* field, with the time-spatial components of a 6-vector (that is, with the subscripts (14), (24), (34)) and the magnetic field with the space-spatial ones ((23), (31), (12)). If you are not alive to the fact (pointed out by Einstein[5]) that this is nothing but a habit, and that the converse association is, *a priori*, at least equally admissible, nay even preferable, you may easily reject a field-theory which is powerful enough to include 'sources'; reject it on the ground that it ostensibly produces them 'in the wrong place' (that is, that it exhibits *magnetic* charges and currents instead of *electric* ones, as are observed).

9. The meson-field. Of even greater moment is the following. Recent research on cosmic rays and nuclear structure leave no doubt that a *third* field exists, of equally fundamental standing with gravitation and electromagnetism: the *mesonic* field, responsible for nuclear binding. To-day no field-theory which does not embrace at least this *triad* can be deemed at all satisfactory.

Now the description of the mesonic field includes (or perhaps just consists of) a 6-vector-field governed by equations, of which Maxwell's are a special case. In fact, the two cases differ classically* only by the numerical value of *one* physical constant, the rest-mass, which is very small, possibly zero, for the 'photon', but very much non-zero for the 'meson'. Quantitatively the difference is enormous. It restricts the *range* of mesonic force to 10^{-13} cm., while electromagnetic force certainly extends[6] beyond 20,000 miles from its source and possibly throughout the universe. But general geometrical field theory, by its very nature, does not prejudice the numerical value of any universal constant. Hence very careful consideration is required here to avoid mistakes.

10. The author's recent attempt. We are now in the position to report succinctly on a recent attempt[7] for which I am responsible. The attitude is exactly the same as that described before as taken by Eddington[3] and Einstein[4] around 1923, namely, the affine connexion (2) is adopted as a primitive notion; the field-equations flow from a Hamiltonian principle, whose Lagrangian density £ is allowed to depend only on the contracted curvature tensor (or *tensors*, see below).

Hence there is no question of a 'new' theory. Yet progress is scored in *two* directions, namely, (i) in freeing oneself, for all general purposes, from the special choice of the Lagrangian £ and (ii) in accomplishing the union of the *three* fundamental fields and, at least, preparing their correct identification.

11. Unspecified Lagrangian. The freedom referred to in (i) above rests on *two* pillars, the first of which is the conviction, gained from other modern research[8], that the fundamental description of, for example, the electromagnetic field, must not be expected to involve just *one* six-vector (usually called B,E) but a second, sort of conjugate, six-vector (usually called H,D) whose components are the partial derivatives of the Lagrange function £ with respect to the components of B,E. From this point of view the field equations can be regarded as provisionally satisfactory even though they still contain those derivatives, and even before the exact functional form of the latter has been made out by deciding upon a special Lagrangian. To make the point clearer: we accept

$$\begin{aligned} \operatorname{curl} E + \dot{B} &= 0 \qquad & \operatorname{div} B &= 0 \\ \operatorname{curl} H - \dot{D} &= 0 \qquad & \operatorname{div} D &= 0 \end{aligned} \qquad (7)$$

as Maxwell's equations, without bothering at first what functions exactly H and D are of B and E.

This attitude cannot be extended to the *gravitational* field, because in this case the physical nature of the two sorts of conjugate tensors is completely known, namely, the *gravitational potential* g_{ik} and the *tensor of gravitating matter* (usually called T_{ik}). The question is, precisely, whether every field other than gravitation gives its expected 'correct' contribution to the matter tensor. We cannot even be provisionally satisfied, before ascertaining that they all do.

This gap is filled by the "second pillar", consisting of 16 *simple identities* between £ and its partial derivatives. These valuable identities flow merely from general invariance, namely, from the trivial demand that the transformational behaviour as a *scalar density* must be forced upon £, when the tensor components of which £ is a function are transformed in *their* way. As I said, these identities fill the gap, they secure that every other field contributes its due share to gravitating matter, whatever £ may be. (This is a special case of the general rule mentioned before, namely, that the conservation laws always follow directly from invariance.)

12. The tensors engendered by the curvature tensor. It is a great relief not to have to decide at an early stage upon the choice of £, when pursuing the second task, the union of the three fundamental fields. To explain the latter we must enter more closely into the tensors on which £ depends, the *contractions* of $B^{i}{}_{k,lm}$.

* At the back of our striving for a unitary field theory, the great problem awaits us of bringing it into line with quantum theory. This point is still covered with deep mist. The present article does not touch on it and has therefore to ignore such features in the conventional description of the physical fields as are concerned with their quantum character; for example, *complex* field variables, the *operators* of spin and isotopic spin, etc.

As mentioned earlier, there are two of them, namely,

$$B^m{}_{k,lm} \text{ and } B^k{}_{k,lm}.$$

The first is termed the 'Einstein-tensor'. It has in general no symmetry and thus splits up into the sum of a symmetrical tensor and a skew-symmetrical tensor (a 6-vector). The second contraction, $B^k{}_{k,lm}$, is always a 6-vector.

We are thus faced with, altogether, one symmetrical tensor of ten components and two 6-vectors—*in admirable agreement with the physicist's desire, who wishes to account for gravitation, electromagnetism and the meson-field.*

But it must be noted that one or the other of these three tensors may be quenched as an independent entity by the special choice of the affine connexion.

In the affine connexion customarily derived from Riemannian metric ($\Gamma^k{}_{ml} = \left\{ \begin{matrix} k \\ lm \end{matrix} \right\}$), *both 6-vectors vanish*. That is why Einstein's theory of gravitation[1] can account for *nothing but gravitation*.

In any *symmetrical* affine connexion ($\Gamma_{ml}{}^k = \Gamma_{lm}{}^k$) the two 6-vectors *coincide* and thus count only as one. That is why the symmetry condition was, with few exceptions[5], adhered to so long as the meson field and its fundamental nature remained unknown.

13. The union of the three fundamental fields. In pursuing the non-symmetric case (though not yet the completely general one) I have reached, along the lines described above, a fully satisfactory unified description of gravitation, electromagnetism and a 6-vectorial meson[7]. The work is far from completed. The completely general case must be tackled, and eventually, of course, the possible special choices for $\mathfrak{L}$ must be examined on their merits. But one point concerning *identification* deserves to be mentioned now.

That 6-vector field which is already obtained with a *symmetrical* connexion and which in all previous attempts was, naturally, identified with electromagnetism, is actually capable of representing either electromagnetism or the meson, according to what value is given to the rest-mass.

The *second* 6-vector field, the one that turns up on dropping the symmetry condition, does not seem to have this equivocal character. It can only be electromagnetism; and that would mean, only it can be electromagnetism.

This means that the meson-field would appear to be an even more fundamental phenomenon than electromagnetism; and that it is even more intimately akin to gravitation, its cousin, as it were. This is just what one would expect, since for all that we know, the mesonic field is produced universally by all gravitating matter, irrespective of its electric charge; whereas the latter is in no recognizable relation to the mass.

INCOMPATIBILITY IN PLANTS

ITS GENETICAL AND PHYSIOLOGICAL SYNTHESIS

By DR. D. LEWIS

John Innes Horticultural Institution

SEXUAL reproduction is essentially the formation of a new individual resulting from the fusion of two gametic nuclei. Any hindrance to this fusion, within the regular mating group, except when it is due to a defect in the nuclei themselves, is said to be due to incompatibility. In many fungi the cells carrying the nuclei are undifferentiated: they are hyphal cells which, when growing together, fuse and transfer nuclei from one to another. In flowering plants, the cells containing the nuclei are differentiated into the male pollen grain and the female egg-cell. The pollen grain is carried to the stigma by wind or insects, and in this position it produces a pollen tube which grows down the style, penetrates the egg-cell and discharges the male nuclei, so that they can fuse with their female partners. Breeding experiments have shown that incompatibility is: (1) always genetically determined, and (2) that it acts to prevent the fusion of nuclei from closely related parents. It is a limiting mechanism which takes many forms both genetically and physiologically. An examination of the meaning and relationship of these forms not only gives a clue to their evolution but also to the action of the genes controlling them.

For the present purpose, incompatibility in flowering plants can be provisionally classified into two systems:

(1) *Incompatibility without heterostyly*, that is, without any floral morphological differences. (2) *Incompatibility with heterostyly*, that is, differentiation into long- and short-styled plants. Self- and cross-pollination within these long- and short-styled plants are incompatible, while pollinations between them are compatible.

The biological efficiency of these breeding control systems has been discussed by Dr. K. Mather[1], and he has concluded that the intervention of diploid tissue, in the form of a style, between the pollen and eggs in flowering plants results in greater efficiency than when this is lacking, as in the fungi. The two systems in flowering plants, that is, with and without heterostyly, appear, however, to have a similar net advantage for the breeding control, although there are slight differences, such as in the amount of sister mating that is permitted by the two systems. The physiology and chemistry of these systems may help to explain the special advantages of one or the other.

Consider first the fungi. The genetical control of incompatibility ('heterothally') in many fungi is based on one or two major genes, each gene having a large number of multiple alleles[2]. This number, as in plants without heterostyly, cannot be matched or even approached by any other series of multiple alleles in plants or animals. Physiologically, two types of incompatibility can be distinguished. In the most common type the hyphæ of the two haploid mycelia, although incompatible because they have one or more incompatibility alleles in common, may grow together and some hyphal fusion may occur. A transference of nuclei may follow; but the nuclei fail to make co-ordinated divisions and thus fail to establish a diplophase mycelium which is essential for spore formation. Furthermore, when a diplophase mycelium is mated with a haploid mycelium, the two nuclei in

the diplophase are quite independent in their reactions to the nucleus of the haploid mycelium[2]. The reaction is therefore one between haploid nuclei.

The less common type of incompatibility in fungi is called hyphal aversion. Here the hyphæ of certain incompatible strains grow towards each other until they are 3–5 mm. apart. At this point they stop growing or grow in the reverse direction. Aerial hyphæ show aversion quite as strongly as hyphæ growing in the culture medium. According to Vandendries[3] the aversion is prevented when metal strips are placed between the averting strains, but strips of glass and mica have no such effect.

Incompatibility without Heterostyly

In diploid flowering plants, the incompatibility reaction is one between haploid pollen grains and diploid stylar and ovarian tissue. The genetical control of this reaction in plants without heterostyly is based on one major gene having a large number of multiple alleles. These are usually designated S_1, $S_2 \ldots S_k$. The pollen reaction, in contrast to that in heterostyly, is under the control of the one S allele in the pollen grain and not of the two S alleles in the soma from which it originates. These S alleles have the action of inhibiting pollen-tube growth in any style that has the same S allele as the pollen grains. For example, S_1 pollen will not grow in a style carrying S_1, but it will grow in all other styles. When compatible and incompatible pollen-tubes grow side by side in the same style, they exert no influence on each other, thus showing that the inhibition is specific to each pollen-tube. The inhibition may sometimes be accompanied by a swelling of the tube end and a thickening of the cell wall, and occasionally by the tube ends becoming surrounded by a diffuse matter with a similar staining reaction to the pollen cytoplasm, although the tube ends show no sign of rupture. These changes are, however, probably secondary effects and not the cause of inhibition, since they do not occur in all cases.

The time and place of inhibition in the style varies according to the species[4]. In *Raphanus sativus* and *Brassica oleracea* germination is affected, in *Oenothera organensis* the tubes stop growing before they have travelled one tenth of their normal distance[5], in *Prunus avium* inhibition is at half way down the style, while in Pyrus and Nemesia it is within the ovarian cavity. Does this mean that the incompatibility activity of the style is localized? This is certainly true for the stigmatic cells of Brassica, since cutting them away removes the inhibition and complete fertility results[6,4]; but this is an exceptional refinement which has not been evolved in other species. Thus, in some species, grafting at different levels two styles, one compatible and the other incompatible with the test pollen, has shown that any part of the style is equally effective in inhibiting pollen-tube growth[7]. Furthermore, the place at which pollen-tube growth stops in the style is affected by temperaure[8]. In all species which have been tested, although compatible tube-growth is accelerated by a rise in temperature, incompatible tube growth is stopped in a shorter time at 25–30° C. than at lower temperatures (10°). This reduction is due both to slower growth and to an earlier stoppage of growth.

Thus it seems that: (1) incompatibility is the result of a reaction between any part of the style or ovarian tissue and the pollen grain or tube; (2) the rate of the reaction is greater at higher temperatures; (3) the products of the reaction accumulate during tube growth causing a lower growth-rate, and finally when a threshold concentration has been reached, complete inhibition.

Diploid styles carry two different S alleles, and just as the reaction of incompatible tubes are independent of one another, these two S alleles in the style are independent in their action on the pollen tubes. This independence, that is, lack of dominance or overriding effect of one allele on another, is also strikingly shown in autotetraploids in which two, three or even four different S alleles can be present. Each allele still exerts its specific effect. For example, a tetraploid style of the constitution $S_1S_2S_3S_4$ rejects pollen carrying any one of these alleles, but all other pollen is compatible[14]. Hence reciprocal crosses between tetraploids and diploids often show differences. For example, the cross $S_1S_2S_3S_4 \times S_1S_2$ is incompatible, S_3 and S_4 alleles in the style having no weakening effect on the reaction of the other alleles; but $S_1S_2 \times S_1S_2S_3S_4$ is compatible, S_3S_4 pollen functioning in an S_1S_2 style. The independence is emphasized by the action of self-fertility (S_F) alleles of the same gene. In Nicotiana, pollen carrying S_F is effective on any style, but an S_FS_1 style will not accept S_1 pollen although all other pollen is acceptable[9]. In *Trifolium repens*, however, the S_F allele appears to have some overriding effect on the normal allele in the style[10].

The significance of this independent action will be referred to later, but one point will be made now. The existence of two independent S alleles in the style implies that the physiological mechanism depends on highly specific and independent reactions, such as are characteristic of protein molecules. Clearly, merely quantitative differences in conditions such as osmotic pressure or pH could not be effective in doing this, because two different osmotic pressures or pH values in the diploid, and four in the tetraploid, would be required in each cell of the style to give the reactions produced by the two or four S alleles.

Pollen grains of diploid plants carry only one S allele, thus interaction of these alleles within pollen grains does not arise; but in the pollen of autotetraploids, of which many new types are now available for experiment, we have the possibility of gene interaction.

Autotetraploids of *Pyrus communis*[11], Petunia species[12] and three Solanum species[13] are fully self-compatible, although the diploids from which they arose are self-incompatible. *Oenothera organensis* is partially self-compatible in the tetraploid form. From the analysis of this effect in *Pyrus* and *Oenothera* it appears that pollen grains which carry two different S alleles are compatible in a style carrying both these alleles[14].

For example, an $S_1S_1S_2S_2$ plant is self-compatible and the pollen segregates both compatible and incompatible grains. It appears that the compatible grains are S_1S_2 and the incompatible grains are S_1S_1 and S_2S_2. Thus the normal action of S_1 and S_2 in the pollen has been suppressed by their interaction. The contrast between the pollen grain and the style in regard to gene interaction is summarized in Table 1.

In the interpretation of Table 1 it should be said that the tetraploids are of recent origin, and therefore have not been subject to natural selection. Natural selection in the diploid has produced independent gene action in the style, an effect which is maintained in the tetraploids. In the pollen grains of

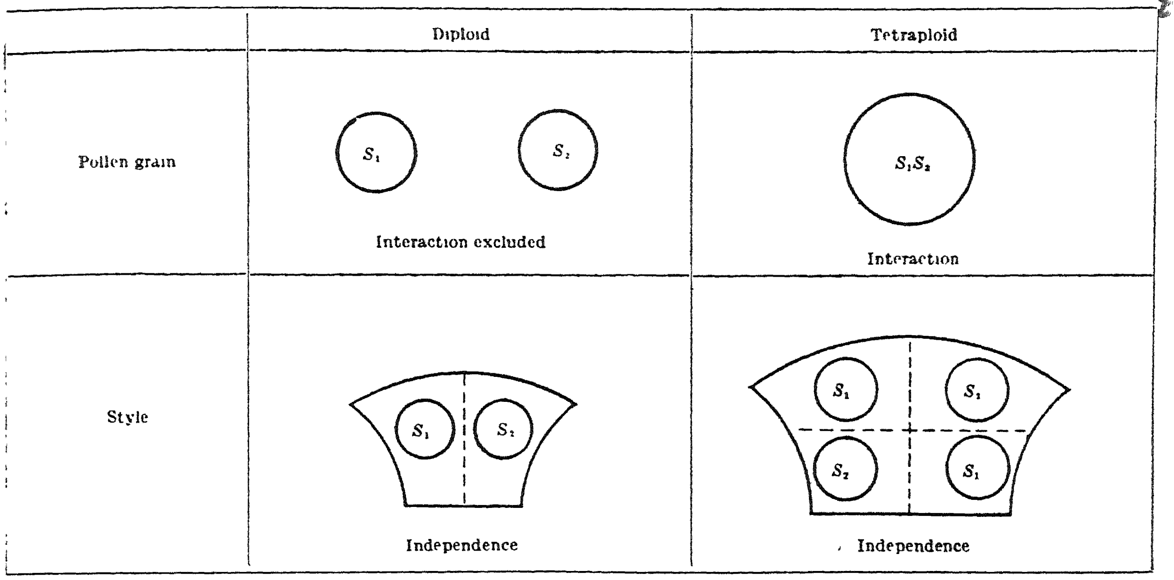

TABLE 1. INTERACTION AND INDEPENDENCE OF S ALLELES, SHOWING THAT TETRAPLOIDY HAS A DIFFERENT EFFECT IN THE POLLEN THAN IN THE STYLE. NATURAL SELECTION HAS BEEN OPERATING IN THE STYLE OF THE DIPLOID, BUT NOT IN THE POLLEN; THIS IS APPARENT ONLY WHEN THERE ARE 2 ALLELES IN THE POLLEN GRAIN.

diploids, although independence is necessary for the system, natural selection has not been operating to produce this effect, since only one allele is present. Hence in the tetraploid gene interaction occurs and the incompatibility system is, in consequence, mainly ineffective.

Incompatibility with Heterostyly

The genetical control of incompatibility in heterostyled plants is based on one gene in distyly and on two genes in tristyly, each gene having two alleles. The pollen reaction is controlled by the diploid soma from which it originates.

Pollen tubes have been examined in three species. In two of these, *Primula obconica* and *P. sinensis*[8], the kind of inhibition of the pollen tubes and the effect of temperature are similar to those in plants without heterostyly. In the third species, *Linum grandiflorum*[15], osmotic pressure differences are the main agent of incompatibility. The osmotic pressure of the style is equivalent to a 20 per cent sucrose solution in the long-styled plants and to a 12 per cent solution in the short-styled plants. The values for the pollen grains are: long-styled plants 50 per cent, short-styled plants 80 per cent. Thus the higher osmotic pressure of the pollen of short-styled plants is suited to the higher osmotic pressure of the long style. The osmotic pressure differences, in the form

TABLE 2. SHOWING THE DEPENDENCE OF POLLEN BEHAVIOUR ON THE OSMOTIC PRESSURE RATIOS OF POLLEN : STYLE IN *Linum grandiflorum*.

		Pollen	
		Long	Short
Style	Long	2·5 : 1 No germination or swelling	4 : 1 Normal pollen-tube growth
	Short	4 : 1 Normal pollen-tube growth	7 : 1 Pollen tubes burst

of a ratio of pollen : style, and the pollen behaviour are given in Table 2.

Both compatible pollinations, long × short and short × long, have a pollen to style ratio of 4 : 1, and here the pollen-tube growth is normal. In the incompatible pollinations, the ratio differs from the 4 : 1 ratio, and this affects the pollen-tube growth in a way which is not found in other incompatible species. Furthermore, temperature has no effect on the incompatible pollen behaviour.

This osmotic mechanism is clearly different in principle from the one in Primula species and in plants without heterostyly, in which differences of osmotic pressure have not been found. It is a mechanism which could be associated only with the genetical control characteristic of heterostyly. The other one, in Primula, may well be analogous to that operating in plants without heterostyly. That two different physiological mechanisms exist among heterostyled species shows that the limitation imposed by the genetical control is less severe in these species than in species without heterostyly.

In fungi we do not yet know enough, but in the two types of flowering plants we can now compare the genetical and the physiological control.

Let us first consider the genetical control. We have seen that haploid control of the pollen reaction, independent action of the S alleles in the style and a large multiple allele series are characteristic of the system in plants without heterostyly; while diploid control of the pollen reaction, interaction with dominance of S alleles in the style and two alleles of one or two genes are always associated in heterostyly. The probable explanation for these associations lies in the adaptive control of gene action and interaction. With diploid control of the pollen and dominance in the style, any effective new mutation of the S gene must not only produce a new type of style-and-pollen reaction but must also have its dominance relations with the other alleles selectively balanced. In these cases a large multiple allele series is therefore very improbable. With haploid control

of the pollen and with gene independence in the style no difficulties of dominance arise, and any new mutation will be at an immediate advantage since it will give compatibility with all others.

It might be argued that the morphological difference in heterostyled plants is the chief restriction on the number of incompatibility alleles; but the answer to this is found in *Capsella grandiflora*[16], which is a species without heterostyly and with all the genetical characteristics of the heterostyled system.

Hypothetical systems constructed with the elements of both the known systems differently combined show that correct adjustment cannot be obtained in another way. For example, a system with haploid control of the pollen, and dominance of *S* alleles in the style will fail, because an *Ss* plant will be self-compatible since the *s* pollen would grow in an *Ss* style. Also in an *ss* × *Ss* pollination only *S* pollen would be compatible. Such a system has so many faults that it could not last long if it ever arose. The reverse of this, that is, diploid control of the pollen and independence of *S* alleles in the style, has the fault that *Ss* styles will reject the pollen of both *Ss* and *ss* plants. It is true that with three or more alleles and special dominance relations between them a perpetuating system can be imagined; but this involves such unusual properties of the gene that it can be disregarded.

TABLE 3. A SUMMARY OF THE GENETICAL AND PHYSIOLOGICAL CONTROL OF INCOMPATIBILITY SHOWING THE RELATIONSHIP BETWEEN THEM.

Morphology	Species	Physiology	Genetics
Not heterostyled	*Oenothera organensis* *Prunus avium* *Nicotiana sanderæ*	(1) Independent gene action in the style but not in the pollen (2) Haploid pollen control (3) No dominance (4) Protein reactions	One gene Multiple alleles
	Capsella grandiflora	(1) Co-ordinated gene action in style and pollen (2) Diploid pollen control (3) Dominance (4) (*a*) Protein reactions (*b*) Osmotic pressure	1–2 genes 2 alleles
Heterostyled	*Primula obconica* *Primula sinensis* *Linum grandiflorum*		

In their physiological control of incompatibility, plants without heterostyly and heterostyled plants differ in a way which reflects the genetical differences. This relationship is summarized in Table 3. Only one mechanism has been found in plants without heterostyly, and this appears to be an immunity type of reaction between specific proteins of the pollen and style. This alone has the possibility of variation necessary to meet the requirements of a large multiple allele series and the specificity necessary for the independent gene action in the style. In heterostyly it appears that this type of reaction is also present in some species; but another mechanism based on osmotic pressure has been found in Linum, and from the genetical evidence there is reason to believe that others exist. Thus a variety of different combinations of physiological and genetical mechanisms have been appropriately combined by selection, in favouring outbreeding modifications of the genetic system which have a long-term evolutionary advantage.

FACTORS IN THE PRODUCTION OF HONEY

By E. B. WEDMORE, C.B.E.

MR. JOHN PRYCE-JONES, who is a physical chemist, discusses "Some Problems Associated with Nectar, Honey and Pollen" in forty-five pages of the *Journal of the Linnean Society* (Pt. 2, 1942–43). This critical résumé will be most valuable to future workers in the same field. A strong case can be made out for further work. The honey bee in Great Britain contributes, by its pollinating activities alone, £4,000,000 a year to the economy of fruit-growing and seed production. An annual expenditure on research of £4,000 would show a return of 10 : 1 if it only increased efficiency by one per cent per annum; incidentally, in the U.S.S.R. the figure is £40,000,000 a year.

Future investigators will need to study far more than the fifty-six principal references cited by Mr. Pryce-Jones. How hard it is to persuade experimenters that the last thing they must do is make an experiment, and the last but one is to record all the circumstances and features that may affect interpretation and application of the results! Many of the researches cited lose permanent value through failure in the latter duty. The conflicting and partial conclusions reached are faithfully dealt with by Pryce-Jones, but many are open to further criticism. For example, there is the investigator who correlates percentage of nectar in fireweed with the humidity of the atmosphere, expressing the results to four significant figures; evidently the arithmetic took charge of the investigator. Having regard to the very large variation disclosed of sugar content with humidity, the meaningless nature of figures given for sugar content without reference to humidity is at once apparent; yet the records abound with them.

Based on the capacity of the bee's honey sac, a round figure of 20,000 flights is quoted for the collection of one pound of nectar. This is converted to 80,000 for honey. Taking the sugar content of honey at 80 per cent, this puts that of the nectar at 20 per cent. Now in the first place, the bee scarcely ever arrives home with a honey sac anything like full; again, a full sac will carry nearly three times the figure quoted; and the figure of 20 per cent is near the lower limit of what interests the bee, and it will generally find a much more profitable source to work upon. It is certain that the figure of 80,000 flights is too high for profitable harvesting. Incidentally, the figure of 200 lb. given as the honey

which a colony consumes in bee production per season and for its own needs before it can show any surplus is on the low side for a really profitable colony.

Miss A. D. Betts has shown that bees can transfer a maximum amount of sugar from a feeder on the hive in a given time when the sugar content of the syrup is about 40 per cent. Thicker syrup is taken too slowly, and thinner syrup carries too little sugar. In the field, the bee spends the larger part of its time travelling to and from the source and from flower to flower. Now if the time occupied in gathering nectar is fixed as part of the whole, Miss Betts' figure is likely to apply; but I infer that for a given strength of nectar the bee will prefer the source in which the nectaries have the larger content, for she will then economize in time of travel. If, however, the sugar content of the nectars varies, it will pay the bee to work at a nectar more dense than that named provided there is more sugar in each nectary; that is, it is the sugar content rather than the nectar content of the nectary that is important and up to limits in excess of 40 per cent. In very dry weather, sugar content far exceeds any figures quoted by Pryce-Jones; indeed, a supersaturated solution is found in very dry weather. In 1942 in Kent and elsewhere, the bees could not work on the limes because the nectar was crystallized.

There is a great deal yet to be done to solve the problems associated with nectar production. No fewer than five theories are quoted and discussed; only one touches upon the relationship of sugar production to soil content; that deals with nitrogen content, but leaves potassium and phosphorus out of account. Pryce-Jones remarks that while the nectary acts as a semi-permeable membrane, holding back the proteins in the sap, no explanation has yet been offered of the diffusion of a dilute solution of sugar in the sap into a more concentrated solution in the nectary.

Pryce-Jones himself has shown that the thixotropy characterizing a very few honeys, notably that from ling and from manuka, is due to the presence of about 1 per cent of a protein. Honey usually contains but a trace of any protein. This particular protein may be extracted and when added to another and liquid honey causes it to become thixotropic. It is difficult to attach much weight to the criticism by Paul 'Espinasse that it has yet to be proved that the protein is of vegetable origin and not added by the bee. Why should all bees add so unfortunate a protein only to those particular nectars, introducing a property which may cause them later to starve in the apparent presence of plenty? It would appear to be far more probable that in these plants a small quantity of a certain protein passes through from the sap. There is room for further investigation of this protein and especially its molecular weight.

In the study of the relationship between the honey crop and the weather, much confusion has been introduced through failure to recognize the large variation of sugar content of nectar when observing changes of hive weight. Certain correlations with weather conditions, however, have been obtained. These indicate that in summer and early autumn, temperatures are generally adequate, but humidity tends to be too low; hence a wide variation in temperature with its wide variation in relative humidity tends to bring the sugar contents within the range for efficient collection for some period of the day, and perhaps to assist in nectar secretion. In the spring, however, temperatures may be inadequate, also hours of sunshine; hence greater importance is attached to temperatures and especially to temperature variation, the latter bringing about periods of suitable temperature and corresponding with periods of intermittent but more adequate sunshine. The conditions are somewhat different as between clay and sandy soils. In studying atmospheric conditions in the summer and autumn, however, there is a correlation factor above 50 per cent outstanding against unknown factors, showing the supreme importance of sources of nectar.

The bee-keeper desires a more continuous succession of adequate sources than he can yet find in any one place; also less unintentional interference by those concerned with agriculture and horticulture. Surely, having regard to the very large contribution to these industries made by the bee-keeper, referred to in the opening paragraph above, it is time that the Ministry of Agriculture assumed official responsibility for bee-keeping, and secured some correlation of the interests of these several industries. A co-operative study, for example, of the benefits to be derived by the several parties by increased use of appropriate sweet clovers, and incidentally of Zofka clover, should provide a very large return for a small expenditure by the Ministry. Any programme should be examined by practical bee-keepers and agriculturists as well as by scientific men if it is to be really effective and profitable. On the practical side, there should be no lack of assistance if only someone in authority would bring the parties together.

OBITUARIES

Dr. J. Argyll Campbell

Argyll Campbell was a most distinguished student at Edinburgh, gaining very many university prizes and honours. He unfortunately suffered early in his career a catarrhal infection which resulted in deafness, a handicap which he most bravely overcame so far as his output of research was concerned, but which prevented him gaining full recognition of his worth. As professor of physiology at the Government School of Medicine, Singapore, he did valuable work, and in the War of 1914–18 prevented the authorities from substituting an equal weight of sweet potatoes (a watery food) for rice in the workers' ration. As one of a small commission, he was largely instrumental in securing the addition of the province of Trengannu to the Malay States.

Returning to Great Britain, Campbell joined the Department of Applied Physiology at the National Institute of Medical Research, where, until ill-health led to his recent retirement, he carried out very valuable research work. An inquiry with me into the protective effect of water-proof clothing against exposure, such as results from shipwreck, resulted in the adoption by the Ministry of Transport of a suitable suit for merchant seamen in the present War; a quarter of a million such suits have been issued, and high value is given to these as the result of experience.

Campbell developed a simple method of measuring the tension of oxygen and carbon dioxide in tissue spaces, and made the interesting discovery that high pressures of oxygen, such as produce oxygen poisoning, occasion a high tension of carbon dioxide in these spaces. The power of hæmoglobin to combine with and carry carbon dioxide from the tissues is thwarted by its saturation with oxygen. He carried out most

important work on oxygen-want at high altitudes, finding that animals could not continue for long to live at altitudes above 20,000 ft. This degeneration has been fully confirmed for man by the experiences reported by Everest climbers such as Mr. Shipton. Although 27,000 ft. has been reached, the incapacity of the climbers is such that there is little hope of Everest being climbed without use of oxygen-breathing apparatus, and that use is beset with difficulties.

Campbell pointed out that one of the means of acclimatization to high altitudes was hypertrophy of the heart. His work on oxygen-want led to the contrivance of a simple but effective oxygen-breathing face mask. With the late Dr. Poulton he published a valuable book on "Oxygen and Carbon Dioxide Therapy", a standard work on the subject. Further researches showed him that oxygen-want is better resisted on a certain diet, such as one of carrots, and this inquiry led to possible means of improving the resistance of high flyers. He also found that the effects of oxygen poisoning at high pressures are warded off by a fall in body temperature; animals are more susceptible at high than at low external temperature.

With me he carried out an investigation of the washing out of nitrogen dissolved in the body by the breathing of oxygen, and the amount of nitrogen in the bone marrow of animals exposed to high air pressures—work of interest in regard to compressed-air illness.

Another important line of inquiry carried out by Campbell was on the effect of inhalation of dust on the production of pulmonary cancer. He found that tar-containing dust from roads greatly increased the frequency of such cancer in mice; dust not containing tar did so also, but to much less extent.

Whatever researches Campbell carried out, of which a few have been mentioned, were executed with the greatest accuracy and thoroughness, so that his results stand unquestioned. He was so deaf that one had to communicate with him by writing, and this fact prevented all but a few from realizing his high worth and modest character. LEONARD HILL.

Mr. E. C. Stuart Baker, C.I.E.

By the death of Mr. Stuart Baker on April 16 at the age of seventy-nine, ornithology, and especially Indian ornithology, has lost one of its most eminent exponents. He was born in 1864; after being educated at Trinity College, Stratford-on-Avon, he followed his father's career in entering the Indian Police Force in 1883. Nearly all his service was spent in Assam, then, even more so than now, a wild mountainous region peopled by primitive and savage tribes, which offered unbounded opportunities for sport and the observation of wild life, of which he took every advantage. He rose to be officiating inspector of police for the Province in 1910; in 1912 he was selected to reorganize the special police force of the Port of London Authority, a post which he held until he retired in 1925.

On his return to England Stuart Baker settled at Upper Norwood and, taking an interest in local politics, he was elected a councillor of the Croydon Town Council, where he served two terms as mayor during 1937–38.

It was not until about the time of his return from India that Stuart Baker began to publish his numerous works on Indian ornithology. These include volumes on the Indian ducks, doves and game-birds, and finally he was asked to prepare a new edition of the birds for "The Fauna of British India" series, issued under the authority of the Secretary of State for India in Council. The first edition by E. W. Oates and W. T. Blanford was in four volumes. Stuart Baker expanded these into eight, published during 1922–30, and practically rewrote the whole. It has since become the standard work on the subject. As he felt he had not done justice, for want of space, to nesting and other habits, he prepared four more volumes, "The Nidification of Birds of the Indian Empire", which appeared during 1932–35.

Perhaps Stuart Baker's most valuable work was on the cuckoo problem. Always deeply interested in the study of birds' eggs, of which he amassed a very large collection, he paid special attention to the cuckoos, especially those of the many Indian and Asiatic species. The results of these observations and reflexions appeared in 1942 under the title of "Cuckoo Problems", in which he discussed such questions as adaptation of cuckoo's eggs to those of the fosterers, how far the 'survival of the fittest' has been concerned in the evolution and adaptation of the eggs, and such lesser questions as the method by which the cuckoo egg has been introduced into the nest of the fosterer and the ejection of fosterers' eggs from the nest by the young cuckoo. The value of this work was greatly enhanced because Baker had at his disposal much evidence from the many Indian species and did not confine himself to the European cuckoo, which had been the case with most previous writers.

Stuart Baker received the C.I.E. in 1932. He was a fellow of the Linnean and Zoological Societies and a member of the British Ornithologists' Union, of which he was honorary secretary and treasurer from 19 3 until 1936.

He married in 1897 Ethel May Roffey, who survives him together with four daughters. W. L. SCLATER.

Mr. J. W. Bullerwell

JOHN WILLIAM BULLERWELL began teaching (two years before he entered college) as an assistant master at the Orphan House School, Newcastle, where he had previously been a student. While an undergraduate at Armstrong College, he taught mathematics and mechanics in Newcastle School Board evening schools, and after graduating in 1896 he became science master at St. Cuthbert's Grammar School and part-time lecturer in mathematics at Armstrong College. In 1901 he became lecturer in mathematics at Hartley College, Southampton, a post which he held only for a short time, before returning to Newcastle as lecturer in physics in 1902, becoming senior lecturer in 1919. He retired in 1938, but returned to duty again until 1942.

Two or three generations of students will remember Bullerwell for his novel and well-thought-out methods of presenting his subject. He was above all other things a teacher, whose every desire was to help and advise his students. He had no grudges against anyone, and he was always ready to rejoice in the promotions and successes of others. With his six feet four inches he commanded discipline with ease, but it was always a parental rather than a dictatorial discipline.

Bullerwell was appointed secretary of the University of Durham Schools Examination Board in 1932, and he carried out the duties with efficiency until

illness forced him to retire in 1942. He acted as treasurer of the Armstrong (later King's) College Choral and Orchestral Society for forty years and in the same capacity for the University of Durham Philosophical Society. The Newcastle Bach Choir was one of his greatest interests, and he was associated with it from the time of its foundation. For many years also he was a member of the committee of the Newcastle upon Tyne Literary and Philosophical Society. He had some reputation as a collector of North Country folk songs, and many people will have pleasant memories of his lectures on the subject.

Bullerwell died on March 17 at the age of seventy.

George W. Todd.

Prof. W. G. MacCallum

Prof. William George MacCallum, the eminent American pathologist, who died on February 3 at the age of sixty-nine, was born at Dunnville, Ontario, on April 18, 1874, the son of a medical man. After qualifying at the University of Toronto in 1894 and at the Johns Hopkins University School of Medicine in 1897, he held the post of intern and later of resident pathologist at the Johns Hopkins Hospital. In 1899 he was appointed assistant in pathology at Johns Hopkins, where he afterwards became assistant professor and professor in pathological physiology and lecturer in forensic medicine. In 1909 he was appointed professor of pathology at the Columbia University College of Physicians and Surgeons, as well as pathologist at the German Hospital and Presbyterian Hospital. In 1917 he succeeded the well-known pathologist Dr. William H. Welch as professor of pathology at Johns Hopkins, and held this appointment until the spring of 1943.

In addition to a "Text-book of Pathology", of which the first edition appeared in 1916 and the seventh and last in 1940, MacCallum's chief publications were on the sexual conjugation of the parasites of avian malaria (1897), the pathology of pneumonia following influenza in the United States during the winter of 1917–18, calcium in tetany (1918), and with Ella H. Oppenheimer "Centrafugalization, a Method for the Study of Filtrable Viruses as applied to Vaccinia". He was also the author of a biography of the surgeon W. S. Halstead.

MacCallum was well known in Great Britain, where he was elected an honorary fellow of the Royal Society of Medicine in 1934. He was also honorary fellow of the Swedish Medical Society at Stockholm, a member of the U.S. National Academy of Sciences, and of the Harvey Society, of which he was president in 1914.

J. D. Rolleston.

We regret to announce the following deaths:

Dr. J. C. Dunlop, formerly registrar-general for Scotland, and an honorary fellow of the Faculty of Actuaries of Scotland, on April 10, aged seventy-eight.

Sir Clement Hindley, K.C.I.E., member of the Advisory Council for Scientific and Industrial Research, and president in 1939 of the Institution of Civil Engineers, on May 3, aged sixty-nine.

Mr. C. B. Rickett, an authority on the birds of southern China, aged ninety-three.

Commander J. A. Slee, C.B.E., chairman in 1938 of the Wireless Section of the Institution of Electrical Engineers, aged sixty-five.

Prof. W. M. Thornton, O.B.E., emeritus professor of electrical engineering at King's College, Newcastle upon Tyne, on May 2, aged seventy-four.

NEWS and VIEWS

Water Supply in Great Britain

A White Paper on water supplies ("A National Water Policy." H.M. Stationery Office, 6*d*.) points out that the problem facing Great Britain is one of organization and distribution, not of total resources, which are ample for all needs. Since water is a bulky commodity, its costs of distribution are relatively high and therefore local sources must be used so far as possible. To do this efficiently will require, not only changes in law and practice, with the co-ordination of the many varied authorities up and down the country, but also a fuller survey of resources than is at present available, and adequate protection against pollution and waste. There must also be a satisfactory supply for industrialists and farmers, who now are normally outside the obligations of public water-undertakings. Agricultural production must no longer be hampered by insufficiency of water and haphazard dependence on casual supplies. The proposals embodied in this report are based on three principles: first, adequate control of water supply services, including changes where they can be justified by greater efficiency or reduction in costs; secondly, responsibility for water supply to rest with democratic bodies ranging from Parliament to local authorities; and thirdly, sectional interests to be subordinate to the national interest, subject to Parliamentary approval.

In the light of these principles, the main proposals of the Government are as follow: the Minister of Health and the Secretary of State for Scotland would be given the statutory duty of promoting the provision of adequate water supply and the conservation of water resources, and their policy would be based on the collection of full information regarding sources and needs. The Central Advisory Water Committee of England and Wales should be reconstituted as a statutory body, and a similar committee set up for Scotland. Survey of the needs of large areas and the efficiency of supplies should be continued, close touch being maintained with town and country planning policies. Amalgamation of water undertakings may be necessary in order to secure efficiency and economy, and also the giving of bulk supplies by one water undertaking to another. Steps must be taken to prevent misuse, waste and pollution. Industry and agriculture are to have the right to water supplies. Compulsory powers, under proper safeguards, should be granted to take water from streams. The Ministers responsible should be given powers to require information and statistics from all users of water and sinkers of wells. The White Paper also contains certain financial proposals; but its main importance is that it considers the problems of water supply on a national basis, and admits the need for rural supplies, even though urban

populations afford the most serious problems in their steadily increasing demands.

The White Paper was discussed on a motion moved by the Minister of Health, Mr. Willink, in the House of Commons on May 3. While the statement received a general welcome, there was criticism from all sides that the suggested procedure was slow and the scheme lacked boldness. Mr. Willink said that the main instrument for collecting information on the yield and quality of water resources is the Inland Water Survey, and the Government proposes to press on with it at the earliest possible date. The Central Advisory Water Committee, with new powers, would advise the Minister of Health on general policy in the light of the information provided by the Survey. As an alternative to this Central Committee, a national water board under a strong, well-qualified chairman, was suggested as a means of co-ordinating the water policy of Great Britain. Against this suggestion it was urged by the Minister of Agriculture, Mr. R. S. Hudson, that water policy touched on too many aspects of national administration, such as housing, health, drainage and agriculture, to make a national water board feasible and practicable.

Regional Organization in Australasia

THE Agreement between the Commonwealth of Australia and the New Zealand Governments signed at Canberra on January 21, 1944, has now been published (Cmd. 6513). In addition to undertaking general collaboration with regard to the location of machinery set up under international organizations such as the United Nations Relief and Rehabilitation Administration, the two countries agree to promote the establishment of a regional organization with advisory powers, which could be called the South Seas Regional Commission, on which the Governments of the United Kingdom, the United States and the French Committee of National Liberation might be represented. Such a Commission would have as its function to secure a common policy on social, economic and political development directed towards the advancement and well-being of the inhabitants themselves and, particularly, the Commission would recommend arrangements for the increasing participation of local inhabitants in administration, with a view to the ultimate attainment of self-government in the form most suited to the circumstances of the peoples concerned; arrangements for material development, including production, finance, communications and marketing; for the co-ordination of health and medical services and education; for the maintenance and improvement of labour conditions and social services as well as collaboration in economic, social, medical and anthropological research.

The publication of periodical reviews of progress in this field is also visualized, and in addition to the establishment of a regional zone of defence and of permanent machinery for collaboration and co-operation between Australia and New Zealand, the Agreement provides for joint action in support of the principles that full control of the international air trunk routes and the ownership of all aircraft and ancillary equipment should be vested in an international air transport authority operating those routes, and that the routes themselves should be specified in an international agreement. Failing such agreement the two Governments support a system of air trunk routes controlled and operated by Governments of the British Commonwealth of Nations under Government ownership.

Colonial Geological Surveys

THE function and future of the Colonial Geological Surveys formed the subject of a recent article in NATURE (153, 273; 1944), in which a discussion on the matter, held under the joint auspices of the Geological Society of London and the Institution of Mining Engineers in November last, was summarized at some length. The subject has again been dealt with in the *Bulletin of the Imperial Institute* (41, No. 4, 255; 1943), by the 'intelligence staff' of the Institute, under the heading "A Review of Geological Survey Work in the Colonies". In this article the authors refer to all the Colonies except those small islands and groups where, it is stated, the question of establishing official Surveys scarcely arises. Particulars are given separately for each Colony as to area, the years, if any, during which geological survey work has been carried out, the amounts of money expended on such work, the staffs employed and the maps that have been published. Reference is also made to the question of water-supply and to mining activities. With few exceptions, it appears that in none of the colonies was a Geological Survey established earlier than 1918. In Ceylon, a mineral survey was commenced in 1903; and in British Malaya a Geological Survey has existed for forty years, though until 1912 it employed only one geologist. In certain other Colonies short-term mineral surveys were carried out in the early years of this century by the Imperial Institute, under the auspices of the Colonial Office.

The information supplied is based on published records, and it certainly provides factual support for the views expressed at the joint meeting of the Geological Society and the Institution of Mining Engineers at their joint meeting last year. It makes it clear, in fact, that there is ample room for enlargement, and improvement in the continuity and scope, of the work of the Colonial Geological Surveys. Actually the matter is in hand, for the Secretary of State for the Colonies has appointed a panel of experts to advise him on the subject. The intention of the authors of the Imperial Institute article is to point out the desirability that a fair share of the Colonial Office grants for the extension of scientific investigation into Colonial problems should be allocated to the expansion of geological survey work. In the view of the Institute, a Geological Survey should be regarded as a public service available to the mining, agricultural and other industries; as well as for government-sponsored public works and water supply services; and also as an educational institute. The association of the Imperial Institute with the Colonial Geological Surveys is one of long standing, and the recommendations made in this article, backed by an authoritative statement of facts, should command the attention of those interested in the welfare and development of the Colonies.

Archæological Find in Kenya

DR. L. S. B. LEAKEY, honorary curator of the Coryndon Museum, who is employed in war-time duties with the C.I.D., Nairobi, has spent eighteen days leave on Site 10 at Mount Olorgasailie in Kenya, accompanied by Mrs. Leakey, Mr. A. J. Arkell, the Commissioner for Archæology in the Sudan, Miss E. Cory, Mr. F. de V. Kirk and Mr. G. Alkin. The excavations carried out showed that the surface indications noted early in 1942 had not been misleading and that the site is of outstanding importance.

The trial trenches that have been dug have revealed that the deposits consist of lake beds alternating with land surfaces. Upon four of the land surfaces—or layers—exposed, there are abundant signs of occupation by Acheulean man, and very large numbers of hand-axes, cleavers and bolas stones have been found closely associated with the fossilized remains of extinct animals. Another discovery of importance is the finding of another occupation floor that represents the first well-authenticated evidence of the existence of a flake-culture people anywhere in East Africa, in the deposits of the Middle Pleistocene. The animal fossils found include those of extinct species of elephant, hippopotamus, giraffe and rhinoceros, a baboon that was as big as a gorilla, and a pig that was as large as a present-day rhinoceros. The Kenya Government has fenced the site, and it is proposed that the various occupation floors shall be exposed and then roofed so that visitors can see the implements and fossils lying in position.

Science and the War

A symposium of papers presented at the seventy-fifth anniversary meeting of the Kansas Academy of Science on April 10, 1943, has now been reprinted (*Trans. Kansas Academy of Science*, 46) under the title "Science and the War". L. E. Cull deals with the place of food and J. H. McMillan with that of physics in the war effort. The latter points out that when Japan began hostilities, the United States had nearly two hundred physicists directing about five hundred professional physicists, investigating specific war problems. This represented about seventy-three per cent of the physicists in the United States who were judged capable and free to carry on this type of work. Both in government research laboratories and in industry there has been an acute shortage of physicists, and the programme for training war-time physicists does not appear to have been so well organized as that for research. N. P. Sherwood's paper on "Bacteriology, Medicine and the War" emphasizes the marked advance in our knowledge and resources since 1928 for dealing with wound infections, venereal disease, typhoid and tetanus, etc.

J. W. Greene, discussing "Chemistry and the War Effort", briefly reviews the familiar achievements of the chemist in such fields as explosives, synthetic rubber, plastics, fertilizers, aviation spirit, solvents, synthetic organic chemicals, etc. "The Role of Botany in War-time" is outlined by P. B. Sears, who refers to the services of botanists in camouflage work, cotton fibre problems, plant breeding and control of disease, the preparation of airfield runways with sod covers which will prevent erosion, and particularly in food production. J. C. Frye and C. P. Kaiser's paper, "Geology in the Present War", refers to the services of the geologist in meeting difficulties in the supply of strategic minerals and other raw materials, domestic water supplies, and in mapping. J. Breukelman deals with the "Relation of Zoology to the War Effort", and refers in particular to its contribution in the field of nutrition, in pest control, in jungle warfare and in the conservation of fauna. The final paper, by H. B. Reed on "Some Contributions of Psychology toward the War Effort", after referring to the neglect of psychology after 1918 by the Armed Forces, indicates the value of the psychologist in placing men in the activities for which they are best qualified and in which they may be of the greatest service to the country, in devising technique for effective training in the skills required in military work or for building up civilian and military morale and propaganda effects, in handling and dealing with children in bombed areas, and in the effective care of war orphans. A brief account of the classification work in the U.S. Army is included.

William H. Nichols Medal of the American Chemical Society : Award to Prof. C. S. Marvel

The William H. Nichols Medal for 1944 of the New York Section of the American Chemical Society has been presented to Prof. Carl Shipp Marvel for outstanding contributions to knowledge of the structure of vinyl polymers, the long-chain molecules used as rubber substitutes, in production of plastics, and as thickening and blending agents in chemical manufacturing, and for his research in the structure of sulphur dioxide – olefin polymers. Prof. Marvel is professor of organic chemistry at the University of Illinois, and president-elect of the American Chemical Society. As a graduate student at the University of Illinois, Prof. Marvel became interested during the War of 1914–18 in the development of synthetic chemicals, at a time when the United States was dependent upon Germany for many drugs and dyes. He is now recognized as one of the outstanding authorities in the United States in organic chemistry, especially in the field of polymers, and for his extensive knowledge of organic chemical reactions. He is also a leader in the development of synthetic methods for making organic compounds, and early in his career at the University of Illinois began manufacturing chemicals needed for research there and elsewhere. One contribution in this latter field was the production of pure amino-acids, which have served brilliantly in vitamin studies and determinations of essentials of diet. The amino-acids also are used for intravenous feeding of persons unable to tolerate proteins. Other work by Prof. Marvel has dealt with the relationship of hydrogen bonding and solubility behaviour, the synthesis and rearrangement of polyenes and polyines, association of free radicals, and other research fields. Prof. Marvel was born at Waynesville, Ill., on September 11, 1894, and received his bachelor of arts degree from Illinois Wesleyan University in 1915. He was a student of Dr. A. W. Homberger, Illinois Wesleyan, and of the late Prof. W. A. Noyes, at the University of Illinois. He has been associated with the editorial board of "Organic Syntheses" since 1923, and with the *Journal of Organic Chemistry* since its founding. He is a member of the National Academy of Sciences, and was chairman of Section B–3, National Defense Research Committee, during most of 1941 and 1942.

Tannic Acid and Burns

The impression that tannic acid is a safe and reliable dressing for burns is nowadays so widespread that there will be much interest in recent experimental evidence suggesting that tannic acid should be abandoned because of the risk of the damage to the liver which it may cause. S. L. Rae and A. W. Wilkinson (*The Lancet*, March 11, 1944, p. 332) studied, by the lævulose-tolerance test, the liver function of 27 children, aged twelve years or less, who had been burned or scalded. Of these children, 12, who had burns covering an average of 17 per cent of the body surface, were treated with 2 per cent gentian violet followed by silver nitrate; and 8 of them, whose burns were smaller, covering an average of 5 per cent of the body surface, were

treated with tannic acid jelly containing one part in 5,000 of merthiolate. Impairment of liver function was least in the group treated with gentian violet and silver nitrate, although the burns in this group were much larger. In a large series of children treated with silver nitrate, there was no case of the acute toxæmia which may occur after tannic acid treatment. Impairment of liver function was commonest and most severe in the group treated with tannic acid. The authors think that this agrees with clinical experience. They suggest that the merthiolate in the tannic acid jelly used may have been partly responsible for the impairment of liver function.

Seven cases with injuries covering 5 per cent of the body surface were treated with sulphacetamide paste, and these occupied an intermediate position between the groups treated with tannic acid and gentian violet – silver nitrate. The authors point out that sulphonamide drugs may be rapidly absorbed from superficial burns and may also cause liver damage; they should be used with care. Their general conclusion is that there is now sufficient clinical and experimental evidence to justify the abandonment of tannic acid as a local application for burns. R. H. Franklin (*The Practitioner*, 62, 167; 1944) also discusses the use of tannic acid and agrees that it is being largely abandoned now. Rae and Wilkinson think that coagulation treatment may save life in the early stages of very extensive superficial burns and that, from the point of view of toxic absorption, silver nitrate is probably a safe coagulant. In an annotation, *The Lancet* (March 11, 1944, p. 344) refers to other experimental work on the toxicity of tannic acid which has been done on dogs, rats and mice, and says: "There seems little doubt now about the experimental facts concerning the toxicity of tannic acid". The *British Medical Journal* (April 1) agrees and adds that, although mortality from burns has diminished since tannic acid was introduced in 1925, there is no evidence that it has "any advantage in this respect over other methods".

Classification of Diseases and Injuries

ASKED by the Ministry of Health to advise on a system for collecting and recording statistics of patients admitted to hospital, the Medical Research Council appointed a Committee on Hospital Morbidity Statistics, which has now issued "A Provisional Classification of Diseases and Injuries for Use in Compiling Morbidity Statistics" (Med. Res. Council, Special Report Series, No. 248. H.M. Stationery Office, 1944. 3*s*. net). The classification here recommended has been adopted by the Ministry of Health for the classification of all Emergency Medical Service records, and the Ministry of Pensions is also using it. It will also be used in the Regional Bureaux of Health and Sickness records which the Nuffield Provincial Hospitals Trust is establishing in some areas. It is comparable with the International List of Causes of Death and the Diagnosis Code of the United States Public Health Service, the code numbers of both of which are included. It is also comparable with the Diagnosis Codes of the Royal Navy, Army and R.A.F. Medical Services. The coding system has been planned for use with mechanical sorting, but may be used equally well with manual filing. It is not suggested that it should replace the Standard Nomenclature of Disease of the American Medical Association.

The Committee has issued this provisional scheme as a Special Report so that it may be available for as wide a trial as possible. Dr. Percy Stocks, in a brief historical introduction, reminds us that every deceased person was either a sick or an injured person and, if his illness is classified during life, it will usually be the same as the cause of death defined in the Registrar-General's Manual. But the bulk of illnesses do not lead to death, so that a classification of diseases and injuries must give greater attention to minor and disabling conditions than a classification of causes of death needs to do. It is recognized that the diagnoses of some diseases, even when they are made by experts, may not agree, so that only tentative groupings are made in some sections. In some groups (for example, heart disease) the classification has been framed with the object of getting information necessary for a better classification. The Committee hopes, indeed, that any errors, omissions or inconsistencies observed will be reported, so that they may be incorporated in a future revised edition.

Value of Human Milk

BRADFORD-HILL has pointed out in his "Principles of Medical Statistics" that bottle-fed babies are 'selected', in that some factor has determined whether or not the mother feeds her baby. Deductions as to the relative values of breast- and bottle-feeding, based on comparisons of growth and health of groups of babies fed by one or other method, are vitiated by this selection. Mr. Eric Wood points out, in an article in the *Medical Press and Circular* of February 9, that no controlled experiment has been made in which the two groups have been comparable at the start, in heredity, environment and physical conditions. Nor is this possible; for readiness to agree to give up breast-feeding would, in itself, make the 'bottle' group a selected one. In default of this possibility, Mr. Wood points out the need for much more information on the following points. (1) The effects of the mother's environment, food, etc., on the ability to suckle and on the quality and quantity of the milk. We now realize that the easy assumption that the mother is sacrificed to the baby does not hold without qualification. (2) The response of babies to their food. Is the flying start of the breast-baby due to the composition of the colostrum? Babies are not, like lambs, dependent on the colostrum for a supply of antibodies from their mothers; antibodies (the antibody to the *Rh* factor, for example) pass through the human placenta. Both flying start and ability to suckle may both be evidence of a superior reproductive capacity. (3) The advantages, if any, of breast-fed babies that persist into later life. Mr. Wood points out that this information would be given only by long-term investigations based "on co-ordinated planning, a long time in advance, by some suitable 'ad hoc' committee or other body". Actually, very valuable work into the composition of human milk has been carried out, for two years, at the National Institute for Research in Dairying, supported by the Medical Research Council; and more extensive investigations, on the lines suggested, had been planned and work on them had started at the beginning of this year.

President Jefferson, Statesman-Scientist

THE recent bicentenary celebrations of Thomas Jefferson's birth have directed attention once again to the versatility of this remarkable man, some of whose special scientific interests are the subject of a 'pre-reprint' of 64 pp., with illustrations and maps, from *Chronica Botanica* (8, Nov. 1943), of a study by

Dr. Charles A. Browne, of the Bureau of Agricultural and Industrial Chemistry, U.S. Department of Agriculture, on "Thomas Jefferson and the Scientific Trends of his Time". The famous statesman-scientist —a type not unknown among the countrymen of Franklin, Rumford, and Hoover, and all too rare elsewhere—was, it appears, not greatly attracted by theory and speculation, which, indeed, he occasionally condemned in severe terms; his scientific interests were largely utilitarian, as is evidenced by many passages from his voluminous correspondence; and his outlook thus admirably fitted him to play the part of scientific scout for America during his residence in Paris as Minister to France (1784–89).

It is interesting to note that during these years in Paris, though he was an eye-witness of the chemical revolution effected by Lavoisier, he was sceptical about the new system of chemical nomenclature. Writing to Madison on this matter on July 19, 1788, he concluded: "The attempt, therefore, of Lavoisier to reform the chemical nomenclature, is premature. One single experiment may destroy the whole filiation of his terms, and his string of sulphates, sulphites, and sulphures, may have served no other end, than to have retarded the progress of the science, by a jargon, from the confusion of which, time will be requisite to extricate us. Accordingly, it is not likely to be admitted generally."

Jefferson's "Notes on the State of Virginia", his magnificent labours in bringing science to the service of the young and undeveloped country in the guidance of the destinies of which he was ultimately called to the highest place, his devoted work for agriculture, and his outstanding services to the cause of science in education, are all well summarized in this interesting memoir.

Stars with Large Proper Motions

A. van Maanen has prepared a paper with this title (*Astro. Soc. Pacific*, Leaf. 176; 1943) which deals with the developments in the discoveries of stellar motions, from the time of Tobias Mayer who determined the motions of several stars in 1760, by comparing his own observations with those of Römer made fifty years earlier. A useful table gives the proper motions of thirty stars with the largest proper motions, in all cases exceeding 3″ annually. Large proper motion suggests relative proximity to the earth, and for this reason it is not surprising that nineteen of the thirty stars are less than 16·3 light-years distant from the sun, and seven are nearer than 32·6 light-years. A very interesting feature in the table is the luminosity of each star, that of the sun being the unit. Only one star—ω Centauri *A*—is brighter than the sun, its luminosity being 1·14. The table also shows that stars with the faintest luminosities belong to the most advanced spectral types and so have the lowest temperatures, with the exception of the white dwarfs. The luminosities of the latter are very low, that of Wolf 489 being only 0·00008.

Electrical Aspect of Farm Mechanisms

A paper on this subject was read in London recently by Mr. C. A. Cameron-Brown before the Institution of Electrical Engineers in which, for the benefit of those interested but not actively engaged in rural electrification, a picture is drawn of the general developments of electrical participation in farm processes; the paper also offers a clearing house of ideas for those actively engaged in rural electrification but whose interest is localized. The paper is devoted chiefly to the less common applications, to those which are the subject of controversy, and to those which may appear to have a wider field of application in the future. Emphasis has been placed on trend rather than on facts and figures; thus Mr. Cameron-Brown covers general trends and observations, specific applications of electricity to farming operations such as grinding mills, threshing, crop drying, milk production and certain special applications. The scope of the paper is confined to general farming—arable, dairy and mixed.

Theodor Puschmann (1844–1899)

Prof. Theodor Puschmann, the eminent medical historian, was born on May 4, 1844, at Lowenberg in Prussian Silesia. He studied medicine successively at Berlin, Marburg, Vienna and Munich, and qualified at Marburg in 1869. He first made a study of psychiatry under von Gudden at Munich and then practised for some years in Cairo. In 1878 he specialized in the history of medicine at Leipzig, and in the following year was appointed extraordinary professor of medical history at Vienna, becoming full professor in 1879 in succession to Prof. R. Seligmann. He died on September 28, 1899. His principal publications were an edition of Alexander of Tralles (1878–79), a "History of Medical Education" (1889) and "Medicine in Vienna during the last 100 Years" (1884). He also wrote the introduction to a great work on the history of medicine which was completed by Prof. Max Neuburger and J. Pagel. His name has been given to a medico-historical institute in Leipzig founded by his wife.

Announcements

The twenty-third Silvanus Thompson Memorial Lecture of the British Institute of Radiology will be delivered by Prof. Sidney Russ on May 20; he will speak on "The Man Silvanus Thompson".

A whole-day conference of the Nutrition Society will be held on May 20, beginning at 10.30 a.m., at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, on "Budgetary and Dietary Surveys of Families and Individuals, Part 2". Papers will be communicated by Miss E. M. Widdowson and Dr. R. A. McCance ("Dietary Surveys by the Individual Method"); Dr. Gertrude Wagner ("Surveys of Methods Used in Preparing and Cooking Foods"); Dr. G. N. Jenkins, Dr. L. W. Mapson and Miss M. Olliver ("Laboratory Assessment of Nutritive Value of Meals as Eaten"); Miss E. M. Langley ("Food Consumption: Data Obtained from Analyses of Institutional Diets: (*a*) School Diets"); Dr. M. Pyke ("Food Consumption: Data Obtained from Analyses of Institutional Diets: (*b*) Industrial Canteens"); Dr. A. Lyall ("Food Consumption: Data Obtained from Analyses of Institutional Diets: (*c*) Hospital Diets"). The openers of the discussion will be Prof. V. H. Mottram, Mrs. Barbara Callow, Dr. C. P. Stewart and Miss M. C. Broatch.

Erratum.—In connexion with the article in Nature of April 29 on "X-Ray Analysis in Industry", Mr. C. W. Bunn states that the concluding sentence on his paper (p. 534, col. 1) should read "This last effect has been observed in polyethylene, and confirmed by the magnetic properties of single crystals of chain compounds".

Molecular Co-ordination in Cellulose

No published hypothesis completely satisfies the evidence on the structure of cellulose, though the approximations derived by workers from Polanyi onwards have provided brilliant essays in reducing chaos to order. What appears to be a closer approximation is described below. A thorough treatment of all the lines of more or less indirect evidence supporting this hypothesis has been held up since the outbreak of war, but the bald description may be of value to those interested in cellulose from other points of view, and may enable those possessing modern forms of atomic models to check the probability of the structure.

In the crystalline structure of cellulose suggested by Meyer and Misch[1], the unit cell contains four glucose residues related by two screw axes. This co-ordination is essentially orthorhombic, with no molecular feature capable of maintaining the distortion to monoclinic form. The latter is also denied by the clear existence of odd orders of $(o\ k\ o)$ diffraction, particularly $(o\ 3\ o)$. Geometrical calculation does not confirm that their assumptions on atomic bond lengths, and angles give a molecular unit that fits into the unit cell—the cellobiose unit is longer than the identity period (b) observed, which is 10·3 A.

The molecular form was reconsidered in view of the studies in the crystallo-chemistry of the sugars by Cox and co-workers[2]. Their view that the five carbon atoms of the pyranose ring are nearly coplanar was expressed in a rigorous model, suited to geometrical calculation, built on the assumption of tetrahedral carbon bonds, with a right angle between the bonds of the ring oxygen. It fits into the cellulose lattice better than the Sachse form of strainless ring, though the details of the structure derived would be improved by making the ring carbons more nearly co-planar, by straining the tetrahedral angles to anything less than 111°.

When the chains are oriented with the principal plane of the rings in the $(a\ b)$ plane of the lattice, the primary alcohol group appears to approach and to form hydroxyl bonds with the pair of secondary alcohol groups of the neighbouring parallel chain. As the chains are related by a pure translation normal to the b or chain axis, this possibility of hydroxyl bond formation is an accidental coincidence due to the particular stereochemical form. If the coincidence were perfect, the orthorhombic symmetry of the $(P_{2_1 2_1 2_1})$ group would be retained. The observed distortion suggests that this uncovenanted bonding is only realized by sacrificing one of the four possible bonds.

In the molecular model, the freely rotating primary alcohol group has an alternative bond, with two oxygen atoms of the same chain. The displacement of the primary alcohol groups on one side of one of the two sets of chains to form this chelate bond explains quantitatively the odd order $(o\ k\ o)$ spots, with the intensities described by Kiessig[3]. It also allows and maintains the slight distortion of the basic $P_{2_1 2_1 2_1}$ cell, to a form which is strictly triclinic P_1.

In a re-examination of the evidence, a different choice from that of Meyer and Misch was made of the b parameter which determines the relative position of the two sets of anti-parallel chains. This new choice better fits the evidence on the regenerated form of cellulose.

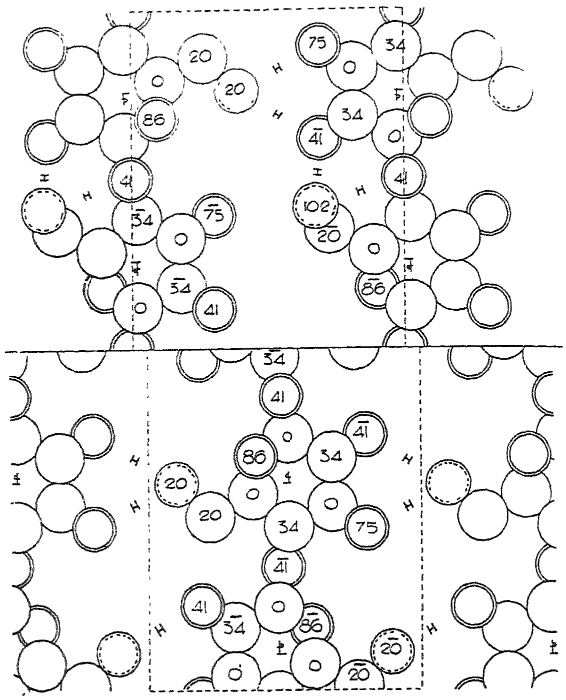

FIG. 1. NATIVE CELLULOSE.

In this form, the pyranose rings are turned from the plane of similarly oriented chains towards the plane containing chains of alternating sense. On general grounds, this is a more normal form of co-ordination, as it gives extra freedom for the formation of local bonds with stringent steric demands. A value of the b parameter in accord with the X-ray evidence produces a model with a series of hydroxyl bond possibilities, best explained by the plan of the cell (Fig. 2). Again such local bonds are necessary to explain the loss of symmetry, from the orthorhombic $(B_{2\ 2_1\ 2})$ cell that would be produced by eight identical units to the observed monoclinic P_{2_1} cell, described by Andress[4].

The regenerated form should be that of lower free energy, as it appears to be from the phenomena of dimorphism. The alternative forms of cohesion between cellulose chains, shown by the two forms

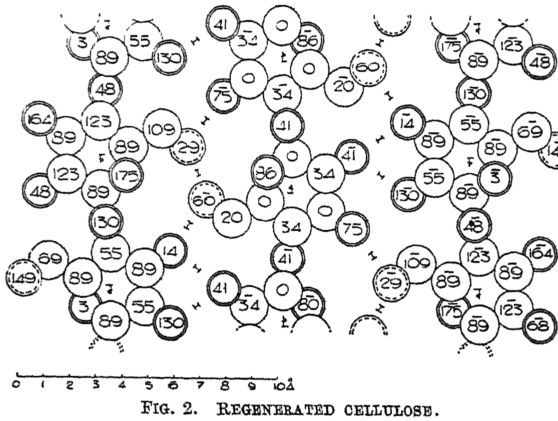

FIG. 2. REGENERATED CELLULOSE.

(which are freely available for local contacts in the deranged regions of cellulose) and the slight distortion from an orthogonal lattice of the crystalline regions (which may occur in either sense to suit the environment) provide a mechanism for the adaptation of the ordered molecular structure to the histology of tissues, and for the production of a strong, but adaptable, continuous lattice work of chains. In such a structure, one can scarcely define strict crystal boundaries; but some statistical description of the distribution in size and locality of the crystallized regions or 'fascicles' is essential for progress in the quantitative theory of fibre behaviour. In particular, the reaction kinetics of polymeric bonds in groups is determined by the size of the group as well as by the energy of the individual bond. This effect of polymeric co-operation explains the striking difference in the physical chemistry of polymers from that of the monomeric congeners.

The molecular structures assigned to cellulose are given in Figs. 1 and 2. Both are projections of the mats of chains on the plane in which the pyranose ring lies, to the scale shown, with normal displacements from the reference plane shown by figures in units 10^{-10} cm., plain above, barred below. In Fig. 1 the plane of reference is the $(a\ b)$ plane of the lattice described by Meyer and Misch; in the top half through the set of chains with chelate bonds; in the bottom half through the set below the first, at a distance $\frac{1}{2}\ c.\sin\beta = 3\cdot 93$ A. In Fig. 2 the plane of reference lies in the plane of the rings in the central chain, normal to the (101) plane of the lattice adopted by Andress (the small monogram in each ring indicates the symmetry operations, and the sign H represents a hydroxyl bond).

The models were constructed by geometrical calculation, assuming the lengths of C–C bond 1·52 A., C–O bond 1·43 A.; the O–O hydroxyl bonds suggested are about 2·6 A. Material models might be cut rather smaller to allow fitting in space.

Molecular Shape and Size of Hyaluronic Acid and Chondroitinsulphuric Acid

THE hyaluronic acid, which was first isolated from vitreous humor[1], and later has been found in, for example, synovial fluid[2] and navel cord tissue[3] gives highly viscous solutions and is often precipitated as fibres. Its molecules have therefore been assumed to have a chain structure. The chondroitinsulphuric acid gives less viscous solutions and is precipitated at most in small fibres of little coherence. Levene and La Forge[4] tentatively expressed its structural formula as a tetrasaccharide, a view which seemed to receive support from von Fürth and Bruno[5], who by the aid of Northrop's diffusion method obtained a molecular weight of about 975.

Both these polysaccharides are rapidly degraded by alkali even at room temperature[6] and are also very easily broken down by oxidative agents[7]. In order to obtain the substances in a state as native as possible, they must therefore be prepared without the use of alkali and excluding air. We have found that solutions of hyaluronic acid and chondroitinsulphuric acid so prepared show a marked double-refraction of flow. The hyaluronic acid preparations were all rather polydisperse. For those isolated from vitreous humor, the particle-length was estimated to about 4800 A. The hyaluronic acid from synovial fluid showed a higher degree of polymerization with a particle-length of about 700 A.; that from the navel cord was still more polymerized, the particle-length lying outside the range that could be estimated with the apparatus used[8]. An extrapolation attempted from viscosity measurements gave a value of the order of about 10,000–12,000 A. These results leave no doubt of the long-chain structure of the hyaluronic acid and, assuming a length of about 10 A. of the disaccharide unit, suggest molecular weights of the order of 200,000–400,000.

The chondroitinsulphuric acid appeared somewhat less polydisperse. The best preparations showed particle-lengths of about 4700 A. This acid, too, has thus without doubt a linear structure, the molecular weight probably being of the order of 200,000.

A detailed report of this work will be published elsewhere.

Lattice Constant of Diamond and the C–C Single Bond

RECENTLY, Lonsdale[1] has published a brief account of her measurements on single crystals of diamond using the divergent beam method[2]. At the same time, measurements were made by me on a specimen of diamond dust employing the X-ray powder method developed to a high degree of precision by Bradley and Jay[3] and others. The two sets of measurements are of interest to the physicist because they provide a comparison of the accuracy obtainable by the powder method with that obtainable by Lonsdale's method; they are of interest to the chemist because they lead to the most accurate value yet of the C–C single bond in diamond.

The specimen was obtained from commercial diamond dust by sieving through a very fine bolting-silk sieve (*c.* 175 mesh). The sizes of the small diamond crystals were therefore in the range 0·01–0·001 cm. approximately. The method used was that described by Lipson and Wilson[4]. The lattice constant of diamond is such that the *K*-radiations of cobalt, iron and manganese are most suitable for precision measurements as they give the 19 β, 16 β and 11 α_1 + 11 α_2 lines respectively at high angles (*c.* 80°). A 19-cm. diameter camera was used; in addition, one photograph was taken in a 9-cm. diameter camera of the van Arkel type. The apparent

lattice constants for the high-angle lines in each photograph were plotted against $\sin^2\theta$, and the result extrapolated to $\sin^2\theta = 1$. In this extrapolation more weight was given to the high-angle values and to the α_1 values as compared with the α_2. It was not considered advisable to use the analytical method of least squares in preference to graphical extrapolation in order to arrive at the best values for a. For if the former method is used, giving an equal weight to each observation, it will give rise to a misleading result; if, on the other hand, different weights are given to the various observations, the method becomes subjective and possesses no advantages over the graphical solution besides being very much more tedious and lengthy. It was, furthermore, obvious from the plots of apparent lattice constants against $\sin^2\theta$ that in each case *all* reasonable extrapolations would give rise to a value of a lying within the region bounded by the limits of error quoted below. The graphical method was therefore adopted. The values obtained, after correction for refraction, are summarized in the accompanying table. The temperature at which the photographs were taken was 18° ± 0·5° C.

Radiation	Camera diameter	a in kX.	Arithmetic mean
Co	19 cm.	$3{\cdot}5595_7$	
Co	19 ,,	$3{\cdot}5595_9$	
Fe	19 ,,	$3{\cdot}5597_8$	$3{\cdot}5596_5$ kX.
Fe	9 ,,	$3{\cdot}5596_1$	
Mn + Cu	19 ,,	$3{\cdot}5597_1$	

The five results are in good agreement and lead to a value for a of 3·5597 kX., the limits of error being ± 0·0001 kX. This is in excellent agreement with Lonsdale's figure of 3·55970 ± 0·00020 kX. (at 18° C.), the variation here referring to different specimens. Dr. Lonsdale gives the limits of error in measuring any *one* diamond as ± 0·00005 kX., which are twice as good as those obtainable by the X-ray powder method and allow her to add a further significant figure. Dr. Lonsdale points out, however, that this very high accuracy is attainable only in exceptional cases, the case of diamond being particularly favourable. This comparison demonstrates the power of the X-ray powder method, which combines the advantages of nearly universal application with simplicity of technique.

The C–C single bond. The C–C bond in diamond is a 'pure' single bond, as there are only carbon atoms present. An accurate knowledge of its length is of interest because it provides a norm from which to measure divergencies from 'pure' single bonding in carbon compounds. Although it has been decided, for the time being, to give lattice constants on the kX. (Siegbahn) scale, it is advisable to quote chemical bond-lengths in Angström units, as they are the basis of spectroscopic measurements. For this purpose a conversion factor of 1·002034 is used[5]. The results, taking Lonsdale's value, are shown below.

a in kX.	a in A.	C–C in kX.	C–C in A.
3·55970	3·56694	1·54140	1·54453
± 0·00020	± 0·00020	± 0·00009	± 0·00009

The C–C bond-length in diamond is therefore 1·5445 ± 0·0001 A.; there is a slight variation from specimen to specimen, but the effect of temperature is small. This value has been arrived at by two completely different methods, and other X-ray measurements[6] on single crystals of diamond are also in agreement. In any one specimen, Lonsdale's method permits a still more accurate knowledge of bond-length; thus, in the specimen measured by her giving a = 3·55974 ± 0·00005 kX., the C–C bond length is 1·54455 ± 0·00002 A.

It is clear that X-ray methods are capable of measuring bond-lengths with very great accuracy in certain cases. An accuracy of one part in 30,000 is relatively easily achieved in the measurement of lattice constants, and where the lattice constant is defined in a simple geometrical way by the bond-length under consideration, this length can be determined with comparable accuracy. Similar measurements are being undertaken for graphite with the view of fixing accurately two points on the order/length curve for C–C bonds.

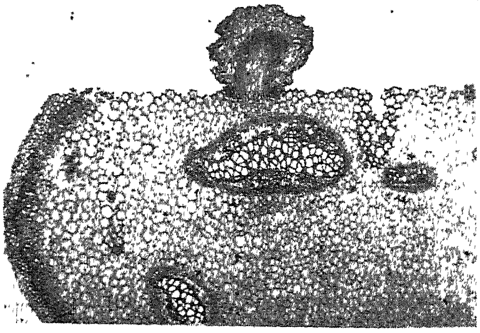
Bud Regeneration at Cut Parenchymatous Surfaces in Onocleoid Ferns

IT has been shown that the removal of the rhizome apex in the ostrich fern (*Matteuccia struthiopteris*) and in *Onoclea sensibilis* is attended by bud development at specific positions along the rhizome. These positions are occupied by superficial areas of meristematic cells, or detached meristems, which at an earlier stage formed part of the apical meristem. Those buds which arise in older regions of the rhizome have no vascular connexion with the shoot stele[1,2].

Two further significant observations have now been made: (1) that if a young induced lateral bud of *Onoclea sensibilis* is excised, new buds may arise from the cavity so produced; and (2) if the superficial tissue containing a detached meristem is removed, that is, as a thin tangential section, from the rhizome of *Matteuccia struthiopteris*, bud development takes place at the cut parenchymatous surface immediately below the position occupied by the detached meristem. This is illustrated in the accompanying photograph: the bud, which is seen to have arisen from a cut parenchymatous surface, occupies a characteristic position, as do induced lateral buds,



Matteuccia struthiopteris. TRANSVERSE SECTION OF AN EXPERIMENTALLY TREATED RHIZOME SHOWING A BUD ARISING FROM THE CUT PARENCHYMATOUS SURFACE. (× 18.) (*Photo. by E. Ashby.*)

opposite a point of meristele conjunction in the vascular system of the shoot; the bud stele ending blindly in the cortical parenchyma.

The potentiality for direct meristematic activity which was known to be present in detached meristems is thus seen to extend locally into the underlying cortical parenchyma also. So far as I am aware, bud regeneration from the cut surface of cortical parenchyma has not hitherto been recorded among the ferns, though a somewhat similar phenomenon has been observed in the genus Lycopodium. These ferns thus appear to afford unusually favourable materials for the investigation of meristematic activity and regeneration phenomena.

A New Antigen of Salmonella

Following the study of a new salmonella type (*S. hormœchei*: XXIX.Z30.—.) made by one of us (M.), which has a flagellar antigen not referred to before (*Z*30), we find it in *S. ballerup* (XXIX.(Vi). *Z*14.—.) and in other salmonella (*LC*54) isolated from Buenos Aires sewage; this new antigen has been named *Z*30.

Natural selection and artificial induction show that this "H" *Z*30 antigen occurs in *S. ballerup* with or without *Z*14. Only after careful selection is it possible to obtain *Z*30 or *Z*14 alone.

The salmonella type obtained from Buenos Aires sewage (*LC*54) presents the curious phenomena of a flagellar phase variation in a new aspect: $Z30 \rightleftharpoons Z14$. This can be demonstrated using the Sven Gard method of artificial induction of flagellar phases. We have named this variation the 'Zeta Variation'.

Another interesting phenomenon has been observed in the *LC*54 strain. When it has the flagellar antigen *Z*30, the somatic antigen observed is XXIX; but when *Z*14 is present, it is not found.

We are continuing the study of the subject, of which the above is a preliminary account of work we have been doing since September 1942.

Production of Seed Potatoes in a Hot, Dry Climate

After Maldwyn Davies's demonstration[1] that low temperatures and high relative humidities were needed to check the flight of the aphids that transmit potato virus diseases, it was widely accepted that these conditions were necessary for growing healthy seed potatoes. The absence of these conditions over most of South Africa, and difficulties in importing seed during the past few years, led to a review of the question, and it has been found beyond reasonable doubt that Davies showed only one side of the picture. Very high temperatures and low relative humidities are as effective as low temperatures and high humidities. At both ends of the scale there is an extreme at which the potato will thrive, but aphids not; it is in intermediate climates that heavy infestations occur.

The first demonstration of the value of a hot, dry climate escaped recognition. Porter[2] showed that at Davis, in the hot Sacramento Valley of California, the spread of virus diseases in potatoes was slow provided that their planting was delayed until mid-summer; and making use of this fact he produced seed for three years which was both healthy and productive. In Australia, Norris and Bald[3] noticed at Canberra that hot, dry weather reduced infestation, but the spells there seem to be too short to be of much use. The evidence in South Africa is that there is an optimum temperature for aphids at which infestation reaches a peak, and that rising temperatures above this optimum progressively reduce the population of aphids until a point is reached at which it virtually disappears. A similar suggestion of an optimum was made by Stepantzev[4]. From observations on the weather conditions favouring infestation of cotton fields in Uzbekistan, he concluded that numbers of *Aphis gossypii* Glov. and *A. laburni* Kalt. were greatest when the mean day and night temperatures were 20° C. (68° F.) and 18° C. (64·4° F.), respectively. Optimum temperatures of about the same order, or a little lower, seem to hold for the aphids *Myzus persicæ* Sulz. and *Macrosiphum solanifolii* Ashm. in potato fields in South Africa; but it is more to the point to determine how high the temperature must be before infestation practically ceases. This happens when the mean daily maximum temperature for the summer months is 32° C. (90° F.), which is the condition in dry, central South Africa around Kimberley. This must not be confused with the highest temperature at which aphids will grow and reproduce in the artificial state of a pure colony in a glasshouse. It refers to field conditions, and is strongly influenced by the host plant. In the field, *Myzus persicæ*, for example, will thrive on cabbages at higher temperatures than on potatoes. Very decidedly, high temperatures will not control all aphids on all crops.

Like high temperatures, very dry air is harmful to aphids, as Stepantzev also pointed out, and is important if seed potatoes are to be grown in hot climates. The Sacramento Valley is in a winter-rainfall zone, and aphids flourish in the mild, moist weather of spring. Consequently, Porter was able to control the spread of virus diseases there only if potatoes were not planted before mid-summer. This allows only one generation a year, which in a hot climate is not enough to stop seed from becoming over-sprouted and stale between harvesting and replanting. At Kimberley, on the other hand, winter rains are negligible; with rising temperatures in early summer the air becomes so dry that aphids are held in check, and there is no dangerous interval between winter and summer. Two crops can be planted, one in August to emerge after the last frost, and one in summer, about January. Since potatoes ripen quickly in a hot climate, these intervals between plantings are enough to allow two generations in one year, with just sufficient time between to sprout the seed.

During the past three years, counts of aphids have been made on thousands of leaves in hundreds of acres of potatoes in all stages of growth at the Vaal Harts and Riet River irrigation settlements near Kimberley. The records are such as few of the world's seed areas apart from the west coast of Ireland could

boast. The average of all counts of *Myzus persicæ* was 1·1 per 100 expanded compound leaves. The highest record was 10 on 275, or 3·6 per 100, compound leaves; this was in April, when the vines were ripening and the danger of virus spreading presumably almost past. Also important is the fact that the life of an aphid in these conditions is so hazardous and short that the vast majority of records were of very young nymphs which could not possibly have transmitted diseases like leaf-roll with a long incubation period in the insect.

To meet the critical shortage of good seed, brought about by reduced imports, action was taken in 1943, and more than 1,000 tons was raised by State production at these two settlements. This found its way throughout the length and breadth of the Union, and in the crucial test of productivity proved to be the best ever available in bulk in the country. The production in 1944 will be still higher; and since yields of seed per acre on the settlements have been excellent, the outlook for the future is bright.

The great limitation of seed production in hot, dry climates is its restriction to varieties in which the symptoms of diseases are not masked by heat. So far, only Up-to-date, South Africa's most popular variety, has been produced in quantity. This is immune in the field to virus *A*: and all diseases to which it is subject (apart from virus *X* with which all commercial stocks are now saturated) remain evident in hot weather, though sometimes in a modified form. A start is now being made with Katahdin.

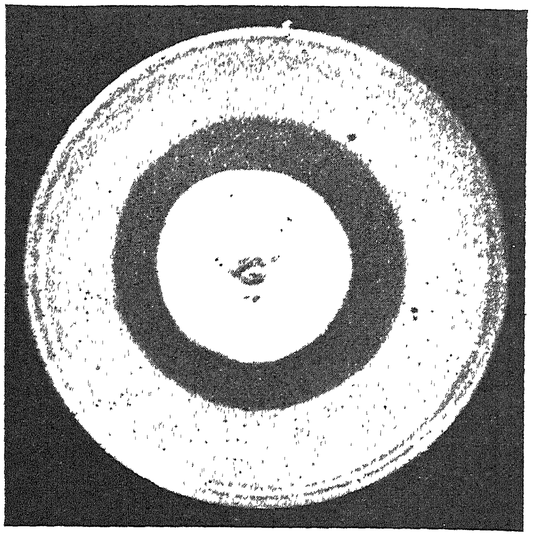
Estimation of the Anti-Bacterial Activity of Fungi that are Difficult to Grow on Liquid Media

THE more detailed work on the quantitative estimation of bacteriostatic substances has been concerned with the assay of penicillin, and the most generally favoured method is the 'cylinder' method as given by Abraham *et al.*[1], amplified by Heatley[2] and discussed by Foster and Woodruff[3]. On beginning our investigation in 1941, the above method was tried but, though apparently satisfactory for its original specific purpose, we found it to be less so for the widespread estimation of the bacteriostatic effect of fungus extracts and metabolism solutions than a method devised by ourselves[4]. Briefly, this method consists of putting a few drops of the liquid to be tested into a circular hole cut in the centre of a plate of bulk-seeded agar medium, with the subsequent production, after incubation at 37° C., of a zone of bacterial inhibition the width of which varies in proportion to the concentration of the bacteriostatic substance. This method only differs from somewhat similar methods mentioned by other workers in that the standardized technique enables it to give a relatively quantitative estimation.

This method has been used for the testing of some



5 MM. ZONE OF INHIBITION PRODUCED BY A 'MYCELIAL DISK' AGAINST *Staph. aureus*.

thousand fungus products of various kinds with complete success; but it is not so useful for the testing of fungi such as the larger Basidiomycetes which are sometimes difficult to grow in culture, usually grow very slowly and do not grow well on liquid media. For fungi of this kind the preliminary test described below will considerably reduce the experimentation time. Assuming a pure culture of the fungus to have been isolated, this is grown as a plate colony on 20 ml. of its most favourable medium. The most generally useful medium is 2 per cent malt extract in distilled or tap water with 2 per cent agar. When the colony has attained a diameter of about 2–2½ in., which may be anything from one to three weeks after inoculation, it may be tested as follows.

Plates are poured containing 20 ml. of nutrient agar to which has been added a suspension of the bacteria against which the test is to be made. Allow these to cool to between 50° and 45° C., then, with a sterile cork-borer, cut from the colony a disk of mycelium and agar and drop it into the centre of the still warm bacterial agar plate. The disk will settle into the agar and the fungus will appear as if it had originally grown there. Incubate at 37° C. overnight. The following morning, if bacteriostatic substances have been produced, there will be a clear, bacteria-free zone around the edge of the disk.

In order to facilitate comparison with the 'hole' method, the mycelial disks are cut out with the same size of cork-borer, namely, 11 mm. diameter. As the medium in the plate containing the fungus colony is always of standard depth, the mycelial disks are of uniform volume. All disks are cut at approximately the same distance from the edge of the colony. The nutrient agar is made up exactly as in the 'hole' method and the concentration of the bacterial suspension is kept as similar as possible.

The advantage of the above method is that, in our experience, the positive or negative result obtained in the test indicates the type of result to be expected if the fungus were to be grown in liquid culture. This shortens the experiment by approximately a month, as the negative fungi can be eliminated forthwith. The method is applicable to any type of fungus, but it is particularly useful for those with a non-sporing mycelium such as the Basidiomycetes, which have

to be grown by the 'disk-inoculum' method. It amplifies, but in no way supersedes, the method in general use in this Laboratory.

Influence of Green Food on the Prevention of Piglet Anæmia

PIGLET anæmia is a microcytic hypochromic anæmia which may affect suckling pigs during the first 21–30 days after birth, especially when they are reared in such a way that access to pasture is excluded. The treatments at present adopted aim at supplying an additional amount of iron to the suckling pigs, either by dosing them individually or by allowing them access to a box of soil which is sometimes dressed with a solution of iron salts.

During the winter of 1943–44, investigations were undertaken to determine the possibility of prevention of anæmia in the suckling pigs by adjusting the diet of the pregnant sows. Four sows which had been running at pasture were housed in concrete-floored styes with open concrete-floored runs one month before they were due to farrow. The following ration was fed at the rate of 6 lb. per day during pregnancy and 10 lb. a day during the lactation period: pollards 60 per cent, beanmeal 30 per cent, fishmeal 10 per cent. To this was added 2 per cent of a mineral mixture containing calcium carbonate 35 per cent, bone ash 35 per cent, salt 18 per cent, ferric oxide (comm.) 12 per cent. Two of the sows received, in addition, two plants of marrow stem kale daily. Weaning of the litters was commenced five weeks after birth.

The litters were weighed bi-weekly and the blood of each piglet was examined at frequent intervals. In the accompanying table are shown the average values for one litter in each group at 2 days, 27–28 days and 51 days.

Age (days)	Erythrocytes (10^6 per c.mm.)	Hæmoglobin (gm. per 100 c.c.)	Packed volume (per cent)	Mean Corpuscular Vol. (μ^3)	Mean Corpuscular Hæmoglobin ($\gamma\gamma$)	Mean Corpuscular Hæmoglobin Conc (per cent)
Group *A* (Kale).						
2	7·01	13·5	50 2	71·6	19·3	26·9
28	5·18	7·0	32·0	61·7	13·5	21·8
51	6·9	11·1	46·5	67·5	16·2	24·0
Group *B* (no green food).						
2	4·61	9·7	34·8	75·5	21·2	28·0
28	5·3	5·3	24·4	46·0	10·0	21·8
51	6·05	7·8	30·5	50·5	12·4	25·7

The piglets in Group *A* remained free from anæmia while those in Group *B* became anæmic.

A preliminary trial is in progress to determine the nature of the factor or factors in the kale responsible for the effects described above.

The above is a summary of the findings of work financed by a grant from the Agricultural Research Council. It is intended to publish the findings in full elsewhere.

Viscosity and Contraction of Unstriated Muscle

THERE is a close resemblance between the effects of ions on the protoplasmic viscosity of simple organisms and plants on one hand and their effects on the viscosity of unstriated muscle on the other. The viscosity of the protoplasm in these simple organisms can be measured by standard methods (for literature see ref. 1), but the viscosity of unstriated muscle is measured by comparing it to known viscous-elastic systems[2,3]; the similarity of the effects on simple organisms and on muscle gives an insight into the structure of the latter, and further establishes the validity of the indirect methods for determining its viscosity.

Sodium and potassium increase, and magnesium and calcium decrease, the viscosity of the *interior* protoplasm of the sea-urchin Arbacia, of the protozoa Stentor and Amœba, and of the alga Spirogyra. In the *cortical* protoplasm of Amœba, calcium causes a pronounced stiffening of the cortical gel, and this effect is antagonized by sodium, potassium and magnesium; potassium has the strongest liquefying effect, magnesium the next and sodium has the least action. Potassium loses its liquefying action in acid solution. The effect of acids is increased in the absence of calcium.

The effects noted above were reproduced in studies of the action of ions on the viscosity of Mytilus muscle. If the sodium chloride of the saline is replaced with calcium, magnesium or potassium chlorides, the viscosity is increased in the order Ca > Na > Mg > K. Indeed, potassium is the most powerful agent I have known for decreasing the viscosity; the effect of potassium is completely counteracted if the *p*H of the saline is reduced to 5 – 4·4. The effect of acid is increased in the absence of calcium. If smaller concentrations of potassium are used (0·1 *M* potassium chloride), then sodium and potassium increase the viscosity, and calcium (0·01 *M* calcium chloride) and magnesium (0·03 *M* magnesium chloride) decrease the viscosity, as in the interior protoplasm of Amœba.

These experiments suggest that plain muscle fibres consist at least partly of undifferentiated protoplasm like that of Amœba. The fact that isolated myosin is effected by temperature, alkalis and distilled water[4] in a similar way as isolated living muscle[3], as described previously, suggests that the contractile element of the muscle consists of myosin.

Plain muscle fibres thus consist of (*a*) a viscous element, (*b*) a non-viscous contractile element. This view is in agreement with (1) the differential action of drugs, (2) the visco-elastic properties, and (3) the histological picture of the muscle. Thus calcium decreases the viscosity of both the guinea pig uterus and Mytilus muscle, but causes contraction of the former and relaxation of the latter. Similarly, hydrogen ions increase the viscosity of Mytilus muscle, but may cause relaxation or contraction. Lastly, histologists have described plain muscle

fibres as consisting of fibrils embedded in sarcoplasm. The contractile fibrils may be disseminated throughout the sarcoplasm, or may be collected into a peripheral zone[5].

Origin of the Planets

THE development of planets from a filament of material formed between two separating stars may not prove so great a difficulty in the theory of the origin of the solar system as is suggested in Dr. Jeffreys' recent letter[1]. It has generally been maintained that the filament would be of such small mass and at such high temperature that its immediate dispersal would occur by lateral expansion. But this view neglects the force field of the two stars transverse to their line of centres, which in the early stages is enormously in excess of the gravitational field of the filament and of enough strength to control thermal velocities due to stellar temperature.

In the lengthwise development, the residual differential attraction of the two stars opposes the self-gravitation of the filament, and to begin with may slightly preponderate, though the two effects are of the same order. At first, pressure differences must urge the matter towards the neutral point, while later the transverse force field of the stars may also be concerned, since during the orbital motion after closest approach their line of centres rotates through more than 90°. The possibility of tidal disruption would not be a fatal objection however, since it is not required that the filament should collect into a single mass. At least three primitive planets must have remained captured by the sun, and possibly others may have escaped, so there seems to be a need for some tendency for the filament to break into a number of masses. But the only worked-out cases of tidal action by stars refer to steady equilibrium forms, and the various forces have unlimited time to operate; such examples do indicate that tidal forces may affect the filament, but they do not enable us to go so far as to say that tidal forces will prevent its gathering into planets.

The situation is in any case much improved as compared with the earlier ideas in that it is sufficient if aggregations form with masses of the order of those of the present great outer planets. There is no necessity for bodies as small as the terrestrial planets to form initially; indeed, the differences of composition of the four inner planets, now ascertained, could scarcely have resulted from simple condensation in the original filament.

There are of course difficulties in the theory, but they are chiefly analytical in nature and are not fundamental inconsistencies involving serious order of magnitude discrepancies. Moreover, the initial hypotheses that lead to material being removed from a star by collision with another, or by rotational instability, have valid observational and theoretical warrant, whereas most proposed alternative starting points are very gravely deficient in this respect. The nebular hypothesis, the planetesimal hypothesis with its bolts shot from the sun, the meteoric swarms, and the lately revived hypothesis of a distended primeval star, all picture initial conditions for the sun that have no support in theory or observation. This is not to say that such hypotheses must be incorrect (though experience shows that they usually are), but they could not be regarded as satisfactory until their connexion with accepted hypotheses had been made clear: that is, until the omitted stages of the theory had been filled in, and this may as well be attempted first as last. Such hypotheses should be preceded by the essential astrophysical investigations demonstrating their legitimacy.

One further point. The central situation of the sun in the solar system is settled by its mass and is not a consequence of the mode of origin of the system. Accordingly, it is not valid to infer from its central position that the sun is necessarily the parent body.

Rate of n-fold Accidental Coincidences

THE time-rate of an accidental coincidence (resolving time t) of n Geiger counters with time rates N_1, $N_2 \ldots N_n$, is most easily obtained by classifying the coincidences according to the counter which goes off first. The time rate of each class is obviously $N_1, N_2 \ldots N_n t^{n-1}$, and hence the total time-rate is

$$R_n = n\, N_1 N_2 N_3 \ldots N_n t^{n-1}, \quad (1)$$

as indicated by Jánossy[1]. The present derivation shows that the formula is *exact* on the understanding that any two groups fulfilling the requirements are counted separately, even when they differ only by one of the n constituent pulses. But physical counting will as a rule distinguish at best such coincidences as differ with regard to all n constituents. That is how the terms of higher order in t mentioned by Jánossy come in. They are sort of a 'correction for overlapping'.

Let us compute the next approximation. The most frequent kind of 'overlapping' (order t^n) occurs when $n + 1$ pulses (two of them from the same counter, say, from No. 1) crowd, so as to contribute *two* coincidences to (1). There are two possibilities. All the $n + 1$ may fall within an interval t. The time-rate of *this* event is, analogously to (1),

$$nN_1^2 N_2 N_3 \ldots N_n t^n. \quad (2)$$

But, in addition, the two No. 1 pulses are allowed to have an interval $t + \tau$, greater than t, provided that the others fall in an interval $t - \tau$, situated midway between the two No. 1 pulses. The time-rate of *this* type of event is easily found to be

$$N_1^2 N_2 N_3 \ldots N_n \int_0^t (t-\tau)^{n-1}\, d\tau$$

$$= \frac{1}{n} N_1^2 N_2 N_3 \ldots N_n t^n \quad (3)$$

The sum of (2) and (3) and of the analogous expressions, with No. 2, No. 3 ... yielding the double pulse, is the correction to be subtracted on the right-hand side of (1). Hence the *next approximation* reads

$$R_n = n\, N_1 N_2 N_3 \ldots N_n t^{n-1}$$

$$\left[1 - \left(1 + \frac{1}{n^2}\right)\left(N_1 + N_2 + \ldots + N_n\right)t\right]. \quad (4)$$

Note added in proof.—The factor n in (2) is a

'howler', as I discovered thanks to Dr. Jánossy's criticism. From elementary principles it must be $\frac{n-1}{2} + 1 = \frac{n+1}{2}$. In (4) you then get the factor $\frac{1}{2} + \frac{1}{2n} + \frac{1}{n^2}$ in lieu of $1 + \frac{1}{n^2}$.

ERWIN SCHROEDINGER.
Dublin Institute for Advanced Studies.

[1] Jánossy, L., NATURE, 153, 165 (1944).

A TREATMENT of the higher order terms of the fold accidental rate is given by Prof. Schroedinger. A treatment leading to a slightly different result follows. Assume that pulses of the counters 1, 2, . . . $n-1$ arrive in the time intervals t_1, $t_1 + dt_1$, . . . t_{n-1}, $t_{n-1} + dt_{n-1}$ with

$$0 \leqq t_1 \leqq t_2 \leqq \ldots \leqq t_{n-1} \leqq t,$$

where t is the resolving time. The above pulses together with one from counter n at the time $t_n = t$ give rise to an n-fold coincidence. The probability per unit time of such an event is

$$P = N_n(N_1 dt_1) \,.\, (N_2 dt_2) \ldots (N_{n-1} dt_{n-1}) \quad . \quad . \quad (1)$$

To obtain a unique classification of the coincidences, we select all those coincidences under (1) for which the pulse of counter 1 in the interval t_1, $t_1 + dt_1$ is the first pulse of this counter to contribute to the coincidence. Both necessary and sufficient conditions for this are that no pulse of the counter 1 should arrive in the interval 0 to t_1. The probability for this is $\exp(-N_1 t_1)$. Imposing similar conditions on the pulses coming from the other counters, one finds,

$$P' = \exp(-N_1 t_1 - N_2 t_2 - \ldots N_{n-1} t_{n-1} - N_n t) \,.\, P, \quad (2)$$

where P' is the probability that the pulses from the counters arrive in specified time intervals and that the first pulses from the counters 1, 2, . . . n taking part in the coincidence arrive in a specified order. The total coincidence rate is obtained by integrating over the t_1 ($i = 1, 2 \ldots n-1$) and summing over the $n!$ permutations of the counters. We thus obtain

$$R_n = N_1 N_2 \ldots N_n \sum_{\text{perm.}} e^{-N_n t} \int\int_{t_1 = t_2 = \ldots t_{n-1} = 0}^{0 \leqq t_1 \leqq t_2 \ldots \leqq t} \ldots \int P' \, dt_1 \, dt_2 \ldots dt_{n-1}$$

$$= \sum_{\substack{\text{cyclic} \\ \text{perm.}}} e^{-N_n t} (1 - e^{-N_1 t}) \ldots (1 - e^{-N_{n-1} t}) \quad . \quad . \quad . \quad . \quad . \quad (3)$$

For $n = 2$ one finds

$$R_2 = N_1 e^{-N_1 t} + N_2 e^{-N_2 t} - (N_1 + N_2) e^{-(N_1 + N_2)t}.$$

Developing (3) into powers of t one finds,

$$R_n = n \,.\, N_1 \ldots N_n t^{n-1} \left[1 - \left(\frac{1}{2} + \frac{1}{2n}\right)(N_1 + \ldots N_n)t\right] + \ldots \quad (4)$$

It is seen that (3) reduces to the expression I gave[1] when neglecting higher powers of t. (The expression for R_n giving the lowest power of t only was also given by Eckart and Shonka[2] some time ago.)

Regarding the practical applications, we note:

(1) In a counter arrangement consisting of n counters, the accidental coincidences are usually due to various overlappings. One has to consider the overlap of a single pulse with a genuine $(n-1)$-fold coincidence; further, one has to consider the overlap of two single counts with a genuine $(n-2)$-fold coincidence, etc. Thus one obtains for the rate of accidental coincidences an expression containing various powers of t. This expression may have no meaning if the higher powers in the terms due to low multiplicities are neglected.

(2) The expression (3) is only valid if the ineffective time following each pulse is short compared to t. In most practical cases, however, the ineffective time will be larger than t. In those cases the expression neglecting higher powers gives the correct rate.

Note added in proof.—The difference between the results as given above and as given by Prof. Schroedinger seems to be connected with the question as to what combination of pulses is recorded as one n-fold coincidence. My picture is as follows. Each pulse sets off the recorder for a time t. Any *connected* period of time for which the recorder is set off by all n counters is counted as 'one coincidence'.

I am indebted to Prof. Schroedinger for an interesting correspondence.

Donnan Membrane Potential

IN a recent communication in NATURE (July 17, 1943, p. 76) I applied the Boltzmann distribution law to the Donnan membrane equilibrium between two compartments, compartment (1) containing colloidal (or non-diffusible) ions plus diffusible ions, compartment (2) containing only diffusible ions. From the equations obtained, it follows that at the same pH of the solution the ratio of the membrane potential (E'_m) for a dibasic acid to the membrane potential (E_m) for a monobasic acid should be

$$\frac{E'_m}{E_m} = \frac{\frac{RT}{N^*F} \cosh^{-1} \frac{3y+z}{3x}}{\frac{RT}{N^*F} \cosh^{-1} \frac{2y+z}{2x}} = 0\cdot66 \text{ nearly,}$$

where y is the concentration of positive, $y + z$ that of negative ions in compartment (1), x the concentration of positive and negative ions in compartment (2), $N^* = \frac{1}{2}(N_1 + N_2)$, N_1 is the valency of the cation, N_2 is the valency of the anion, and z is *small*. At the same pH value of the solution, z in the case of sulphuric acid is not equal to z in the case of hydrochloric acid. According to Donnan, at the same pH of the protein solution, the value of E'_m/E_m has been given as $\frac{2}{3}$. or 0·66 by Loeb. But this ratio should be 0·66 nearly, since the value of z is different in the two cases.

ACTIVATION OF PYRETHRINS IN FLY-SPRAYS

By W. A. L. DAVID and P. BRACEY

London School of Hygiene and Tropical Medicine

MOST mosquito- and fly-control sprays contain pyrethrins, so that, during the present shortage, methods of economizing pyrethrins are of considerable importance. One accepted method of effecting an economy is to add to the spray a small proportion (usually less than 5 per cent) of a material which although not insecticidal in itself yet has the property of making the pyrethrin spray a great deal more effective. Such non-toxic additions are commonly called adjuvants or activators; for example, *iso*-butylundecylenamide[1] and sesame oil[2]. So far as we are aware, this phenomenon of activation has never been explained, and indeed certain observers have experienced difficulty in demonstrating its existence.

We have recently had occasion to examine the efficiency of many spray formulæ containing adjuvants. The method used consisted of exposing the test insect *Aëdes aegypti*, reared under standard conditions, to the spray-mist produced in a cabinet maintained at 28° C. and 70 per cent relative humidity. An Aerograph M.P. paint spray-gun adjusted to produce a finely divided mist served as the atomizer. A sample of the mist mechanically deposited showed that when odourless distillate was sprayed at 0·5 oz. per 1,000 cu. ft., practically no droplets above 7·5 microns in diameter reached the sampling apparatus at the end of the first minute after spraying. The insects were introduced into the cabinet four minutes after spraying, enclosed in paper-walled cages having wide-mesh gauze ends, through which the mist penetrated. They remained in the cabinet for ten minutes.

With the test system outlined we have come to the conclusion that: (1) The four activators tested delay the occurrence of 'knockdown' and so prolong the period of flight through the mist. As the activator content of the spray is increased, within limits there is a progressive increase in the percentage kill recorded, and at the same time a progressive delay in the occurrence of knockdown. These statements may be illustrated by data on *iso*butylundecylenamide.

Insecticide	% Knockdown (min.) 2	4	6	8	10	Av. percentage kill after 24 hr.
Pyrethrins, 0·1 % wt./vol.	10	95	100	100	100	50
Pyrethrins, 0·03% wt./vol.	5	20	97	100	100	20
Pyrethrins, 0·03% wt./vol.; *Iso*butylundecylenamide, 0·50% wt./vol.	0	10	40	95	97	27
Pyrethrins, 0·03% wt./vol.; *Iso*butylundecylenamide 1·50% wt./vol.	0	5	15	75	95	55

(2) The insect picks up its dose of insecticide by impaction with the spray droplets during its period of flight through the mist. Since this is the case, the delay in the occurrence of knockdown gives the insect a greater chance of picking up a heavy dose of insecticide. The importance of flight through the mist is confirmed by two observations. Insects in the following conditions were exposed to the spray mist simultaneously: (*a*) not chloroformed; (*b*) chloroformed and recovered; (*c*) chloroformed but wings were removed before recovery; (*d*) chloroformed—still motionless when exposed. Unsprayed chloroformed controls all recovered.

State of insects	Average percentage kill after 24 hr.
Not chloroformed (*a*) ..	62
Chloroformed and recovered (*b*)	58
Wingless (*c*)	13
Under chloroform (*d*) . ..	12

The low kill with the walking (wingless) and motionless insects will be noted in comparison with that of flying insects. (Another possible suggestion, which is, however, largely discredited by observation 3, is that there was greater intake of spray mist through the spiracles of the flying insects due to increased respiratory exchange.

(3) The rate of movement of the insect in relation to the droplet and the relative momenta are important. The test procedure was modified so that the spray mist moved past insects which had been chloroformed at known speeds. The same total volume of atmosphere was passed over the insects in the two cases below.

Wind speed m.p.h. (approx.)	Average percentage kill after 24 hr.
0·3	8
3·0	97

(4) Activation of sprays by adjuvants can be demonstrated by the method outlined in (3) above. Here the insects do not fly through the mist, hence prolongation of the period of flight (discussed in (1)) is not the only factor in activation.

Insecticide	Average percentage kill after 24 hr. (wind speed 3 m.p.h. approx.)
Pyrethrum, 0·10% wt./vol. ..	96
Pyrethrum, 0·05% wt./vol. ..	53
Pyrethrum, 0·05% wt./vol.; activator, 5·00% wt./vol.	100

In the above table the activator may be either sesame oil, *iso*butylundecylenamide or lubricating oil; in all cases the kill obtained was 100 per cent.

(5) All the above-mentioned activators have a very marked effect on the particle size and persistence of the insecticidal mist. This is due not to the slight effect on the degree of atomization originally produced at the spray-gun nozzle, but to the fact that all the activators are substances of low vapour pressure, so that they persist when the more volatile carrier has evaporated. A comparison of non-activated and activated mists mechanically deposited ten minutes after spraying from an atmosphere dosed with approximately 0·5 oz. per 1,000 cu. ft. shows that, whereas the former contains few droplets per litre 5 microns or bigger, with an activated spray mist there are very many thousands. Further measurements of size and persistence are being made, and at this stage satisfactory figures cannot be given.

(6) Following the observation of the effect of an activator on particle size, it was expected that many substances of low vapour pressure would show this kind of activation. This has been found to be the case with olive oil, oleic acid, sesame oil free from sesamin and lubricating oil, for example.

Insecticide	Average percentage kill in 24 hr.
Pyrethrins, 0·05% wt./vol. ..	12
Pyrethrins, 0·10% wt./vol. ..	65
Pyrethrins, 0·50% wt./vol.; oleic acid, 5·00% v./v. ..	89
Pyrethrins, 0·50% wt./vol.; olive oil, 5·00% v./v.	73
Pyrethrins, 0·50% wt./vol.; lubricating oil, 5·00% v./v.	80
Pyrethrins, 0·50% wt./vol.; sesame oil free from sesamin, 5·00% v./v.	81

From the cabinet tests there seems to be little doubt that two of the factors which contribute to activation are (1) prolongation of the period of flight through the mist; (2) increased persistence of droplets of the order of 10 microns in diameter.

This physical explanation of activation does not cover the whole of the facts. For example, the observation of Haller *et al.*[3] that pure sesamin at 0·2 per cent is capable of acting as an effective activator against the housefly, whereas certain allied substances fail, is not covered.

We have been able to show activation against *Aëdes aegypti* with pure sesamin and, as mentioned earlier, with desesaminized sesame oil. The occurrence of knockdown is also delayed by pure sesamin.

Insecticide	%Knockdown (min.) 2	4	6	8	10	Av. percentage kill after 24 hr.
Pyrethrins, 0·05% wt./vol.*	2	40	95	100	100	36
Pyrethrins, 0·05% wt./vol. } * Sesamin 0·20% wt./vol. }	0	20	60	95	100	75

* Both dissolved in 10/90 v./v. mixture of acetone and kerosene.

When sesame oil, *iso*butylundecylenamide or lubricating oil is used in the spray formula, the resulting droplets after evaporation consist of a solution of pyrethrins in a medium which is considerably more viscous than that resulting from an unactivated spray. They are also less concentrated. It was originally thought that the higher viscosity and lower concentration of pyrethrins in the droplets (resulting from the activated spray) delayed the penetration of pyrethrins and so the occurrence of knockdown. However, this explanation does not account for the delaying effect shown by sesamin and so probably has little validity.

When a spray droplet evaporates, non-volatile insecticides persist as sub-microscopic particles, as may be shown by spraying a dyed oil and mechanically depositing the resulting mist after four minutes. A cloud of dye, unassociated with oil, is obtained. Under suitable conditions the particles which persist when using any of the activators mentioned here, except sesamin, are of the order of 1–10 microns, and within this range impaction occurs at lower velocities. It appears that there is an optimum final droplet size for securing a maximum kill. If the droplet is too small, impaction with the insect does not take place; whereas if it is too large, the toxic principle is rapidly lost from the air space by sedimentation. Here it may be noted also that, for a given activator content of the spray, the final droplet size will depend upon the size of the particles produced by the atomizer. Theoretically, therefore, it would be expected that for an atomizer giving a coarse spray a lower activator content would be required than for a fine spray, since after evaporation the coarse spray leaves a residual droplet which may be so large that it will be rapidly lost by sedimentation.

At the time of writing we have some evidence that activation becomes more apparent as the degree of atomization produced by the gun increases. Finally, it is perhaps worth emphasizing that only *Aëdes aegypti* has been employed in these tests, and that the conclusions may not hold good for other insects.

This work is being carried out under a grant from the Medical Research Council.

THE CEDAR TREE

By ALEXANDER L. HOWARD

ALTHOUGH the cedar tree is not indigenous to Great Britain, it has been established so long and has become a peculiar and ornamental feature of our parks around country houses, churches, and rectories, and so much admired that its absence would be a grievous loss. It is safe to affirm that up to seventy years ago very many thousands of trees could be counted throughout the country. During this period many have been destroyed, blown, or cut down, and it would be difficult to count up to four figures the numbers which have been replanted. Unfortunately, in too many cases a little cedar tree was planted close to the house, the original owner failing to recognize that the time would come, and that soon, when the cedar tree would top the house, so that additional loss has been caused by so many fine trees of this character having to be sacrificed.

The cedar is reared with difficulty. Many years ago the capable gardener at Mill Hill School told me that it had taken him several years—I think from six to nine—before he had been able to raise one tree from the well-known Linnean cedars there. William Boutcher in "A Treatise on Forest Trees", dated 1776, says:

"The way that was first practised for procuring their seed, was by splitting the cones length-ways through the centre, with a sharp piece of iron, and to pick them out with your fingers, which may be easily done, after the cones have been exposed some hours before a warm fire. Should the cones be two years old, they will emit their seed more freely than when just gathered, and the seed equally good.

"The best soil to raise these plants in, is that of a rich old cow pasture, which, if not naturally of a light quality, must be mixed with a fourth or fifth part of sea-sand, or that taken from the sides of rivulets, to be well blended together for some months, before it is used. I have already mentioned that this tree will not require any attention after it has arrived to the age of three or four years, nor is it very delicate from the beginning; yet at the same time, it is absolutely necessary to give them abundant nourishment at first, in order to raise a fair and vigorous plant; for if they once become dwarfish, stunted, or to lose their leading shoot, no art will be possible ever afterwards to restore them to a good figure."

Strutt says, in 1830, while mentioning that the cedar has not been much cultivated in England until of late years:

"its quick growth and its capability of thriving in a meagre soil, renders it peculiarly desirable for those bleak and barren situations which have hitherto been principally devoted to the fir. The frequent and solemn allusions to the Cedar in Holy Writ, seem to give it something of a sacred character; which is increased by a knowledge of the esteem in which it was held by the ancients, on account of its fragrant scent, its incorruptible nature, and above all its durability, insomuch that it is recorded that in the Temple of Apollo at Utica, there was found timber of Cedar nearly 2,000 years old."

From the financial aspect, no satisfactory result can be expected, and suitable sites for planting will be increasingly difficult to find. Only an enthusiastic desire on the part of those who might be able to re-afforest the country with this noble tree can prevent its final disappearance.

There is only one true cedar.

Quoting from "Timbers of the World":

"Under this commercial name (cedar) a motley collection of woods is included. In the first place comes the true cedar, a coniferous genus, Cedrus, of which there are three species or varieties: the cedar of Lebanon, the deodar, and the Mount Atlas cedar. Another coniferous type, the Port Orford cedar (*Cupressus Lawsoniana*), should more correctly be termed a cypress, for the tree is familiar in gardens under the name of Lawson's cypress. The pencil cedars, being the wood of several American species of Juniperus, are truly junipers and likewise conifers. All these woods possess a very fragrant scent. It is not surprising that the name cedar has popularly, and hence commercially, been attached to the cigar-box, a West Indian wood derived from a tree (*Cedrela odorate*) which is in no way allied to Cedrus but is a member of the mahogany family (Meliaceae). Other species of Cedrela, including the Indo-Australian *C. Toona* and *C. australis* and the Paraguayan cedar *C. braziliensis*, are more or less fragrant and receive the name cedar.

"The wood of Cedrela in many respects resembles mahogany, and has to some extent similar characteristics, so that the name has been extended to various American, African, etc., woods, which more or less resemble in appearance those of Cedrela, though not necessarily possessing any fragrance or strong scent. Some of the woods belong to the mahogany family, some do not, while the sources of still others are unknown. Then again there is in British and Dutch Guiana the so-called cedar, the product of *Protium altissimum*. The tree is not a cedar, nor has it any of the characteristics, and it is entirely without the fragrant scent usually associated with that wood.

"Further confusion arises owing to the fact that between mahogany and cedar woods of the Cedrela type there exist transitional forms, which are termed mahoganies or cedars according to the will of the vendor."

There are three different kinds of true cedars belonging to the genus Cedrus. The differences between them are so slight and fluctuating that all three are frequently included under one botanical name, *C. Libani*: sometimes, however, each is given a separate name. All are mountain trees; the first-named growing on Mount Lebanon, in Cyprus, and the Orient; the second being Himalayan, and the third African and growing on the Atlas Mountains. All these are grown in English gardens. The timbers of the three kinds are almost indistinguishable. An easy way of identifying the varieties has been mentioned to me, though it should be taken as general and not absolute: L. for Libani, l. for level (the branches extend from the tree in a more or less horizontal manner); D. for Deodar, d. for drooping (the branches generally droop); A. for atlantica, a. for ascending (the branches generally slope upwards).

Besides the references to cedar wood in the Bible, and in the earliest Greek and Roman writings in their poetry and prose, Pliny says:

"As for Cedars, the best simply be those that grow in Candie, Affricke, and Syria. This virtue hath the oil of Cedar, that if any wood or timber be throughly anointed therewith, it is subject neither to worm nor moth, ne yet to rottenness. The Juniper hath the same properties that the Cedar. They prove in Spain to be exceeding big and huge, the berries also greatest of all others. And wheresoever it groweth, the heart thereof is more found than the Cedar. . . .

. . . "the kings of Egypt and Syria, for default and want of Fir, have used (by report) instead thereof Cedar wood about their shipping. And verily the voice goeth of an exceeding big one which grew in Cyprus, and was cut down for a mast to serve that mighty galleace of king Demetrius, that had eleven bankes of oares to a side; a hundred and thirty foot it was high, and three fatham thick. And no marvel, since that the pirates and rovers who haunt the coasts of Germanie, make their punts or troughs of one entire piece of wood and no more, wrought hollow in manner of a boat, and some one of them will hold thirty men."

Although we have evidence that some of the wood of the true cedar was actually used, it is probable that by far the greater number referred to other scented woods. No greater confirmation of the above confusion over the name can be advanced than the interesting and informative remarks contained in Pliny's Discourse. He says:

"The great Cedar, called by the Greekes Cedrelate, as one would say, the Fir-Cedre, yieldeth a certain pitch or paraffin named Cedria, a singular medicine for the tooth-ache; for it breaketh them, fetcheth them out of the head and easeth all their pain. . . . This kind of pitch were excellent for the eyes but for one discommoditie, in that it causeth headache. It preserveth dead bodies from corruption, a world of years: contrariwise, living bodies it doth purifie and corrupt. A strange and wonderful propertie, thus to mortifie the quicke, and quicken (as it were) the dead. It marreth and rotteth apparell, as well linnen as woollen: and it killeth all living creatures."

And further:

"Also the Phœnicians have a lesse kind of Cedars much like to the Juniper; and two sorts there be thereof, the Lycian and the Phœnician, which differ in the leafe: for that which hath an hard, sharpe, and prickie leafe, is called Oxycedrus: full of branches it is besides, and so knurrie, that it is troublesome to the hand. As for the other Cedar, it hath an excellent smell. . . . And the timber of it is everlasting: wherefore in old time they were wont to make the images of the gods, of this wood, as it appeareth by the statue of Apollo Sofianus, made of Cedar wood, brought from Seleucia. In Arcadia there is a tree like the Cedar, but in Phrygia it is called a shrub."

We might be in doubt, since Pliny describes the tree, using the word "fir", but afterwards he speaks of "berries" and "fruit", which while it is a true description of the foliage, is not a description of the cones of cedar of Lebanon. It is possible that the translation from Pliny's Latin to our language explains the point, as Strutt in his "Sylva" sets all doubts at rest when he refers to cedar of Lebanon and further says:

"It entered largely into the construction of the most celebrated buildings of antiquity; and in the glorious Temple of Solomon it seems to have been recorded of it, as one of its proudest boasts, that 'all was Cedar; there was no stone seen'.

Elwes says the cedar was introduced into England during the seventeenth century, and quotes Loudon "who held the Cedars at Chelsea mentioned . . . in England". But he says further that Mr. Challis informed him that he counted 236 rings on the Hammersmith tree when fallen, which would date the introduction back to 1638. Strutt mentions the Hammersmith Cedar, which at the time he wrote measured 16 ft. 6 in. in circumference at the ground, 59 ft. in height, and branches covering an area of 80 ft.

According to Dr. Hunter in his notes in Evelyn's "Silva":

"The trees in the Apothecaries Garden at Chelsea were planted in 1683. In 1774 they had attained a circumference of 12½ feet at 2 feet from the ground, while their branches extended over a circular space 40 feet in diameter. 27 years afterwards the trunk of the largest one had increased more than ½ ft. in circumference: this shows the quickness of its growth in proportion to that of the Oak, which in the same period would probably not have made half that progress."

Strutt says:

"The Enfield Cedar stands in the garden of the Manor House, or old Palace in Enfield, the occasional retirement of Queen Elizabeth before she came to the throne, and the frequent scenes of her royal pleasures afterwards, in the early part of her reign. In the year 1660 it became the residence of the learned Dr. Uvedale, master of the Grammar School of Enfield at that time, and famous for his curious gardens and choice collection of exotics. The Cedar, which is now perhaps the largest in the kingdom, was put into the ground by him, a plant brought direct from Mount Libanus. In 1779 it measured 14 ft. 6 in. at the base, and 45 ft. 9 in. in height, 8 ft. of the upper part having been broken off by a high wind in 1703. The principal branches extended in length from the stem from 28 to 45 ft., and the contents of the tree, exclusive of the boughs, was about 293 cubic feet. In 1821, Dr. May, its present proprietor, and the master of the Grammar School at Enfield, took its measurement, which was as follows: 17 ft. in circumference at 1 ft. from the ground, 64 ft. in perpendicular height, and containing 548 cub. ft. of timber, exclusive of the branches, which from north-east to south-west extend 87 ft. and contain about 250 ft. of timber, making in the whole nearly 800 ft. of timber."

A remarkable cedar (*Cedrus Libani*) at Brockett Hall, in full vigour of life, measures 18 ft. in circumference, with fine healthy bark to the height of 20 ft., where it branches out with huge limbs. The total height is 80 ft., and from the crown there are nine branches averaging 35 ft. long, each 4–5 ft. in circumference, giving a roof span of 62 ft. It is a beautiful specimen, having regard to its great age. At Brockett Hall there are 85–90 cedars in the Park, of which 45 or more are *C. Libani*, 2 *C. Deodara*, and about 40 *C. atlantica*.

The Rev. C. A. Johns gives an interesting account of the introduction of the cedar tree into France, as follows:

"Many years ago a Frenchman, who was travelling in the Holy Land, found a little seedling among the Cedars of Lebanon, which he longed to bring away as a memorial of his travels. He took it up tenderly, with all the earth about its little roots, and, for want of a better flower-pot, planted it carefully in his hat, and there he kept it and tended it.

"The voyage home was rough and tempestuous, and so much longer than usual, that the supply of fresh water in the ship fell short, and they were obliged to measure it out most carefully to each person. The captain was allowed two glasses a day, the sailors, who had the work of the ship on their hands, one glass each, and the poor passengers but half a glass. In such a scarcity you may suppose the poor Cedar had no allowance at all. But our friend the traveller felt for it as his child, and each day shared with it his small half glass of precious water; and so it was, that when the vessel arrived at the port, the traveller had drunk so little water that he was almost dying, and the young Cedar so much that, behold, it was a noble and fresh little tree, six inches high!

"At the Custom-house the officers, who are always suspicious of smuggling, wished to empty the hat, for they would not believe but that something more valuable in their eyes lay hid beneath the moist mould. They thought of lace, or of diamonds, and began to thrust their fingers into the soil. But our poor traveller implored them so earnestly to spare his tree, and talked to them so eloquently of all that we read in the Bible of the Cedar of Lebanon, telling them of David's house and Solomon's temple, that the men's hearts were softened, and they suffered the young Cedar to remain undisturbed in its strange dwelling. From thence it was carried to Paris, and planted most carefully in the Jardin des Plantes. . . . The Cedar grew larger and larger, and became the noblest tree there."

Those who have only seen cedars in England, or even been fortunate enough to have visited Mount Lebanon, can have no conception of the glory of these trees in the Himalayas. The late Sir George Hart, inspector-general of forests, made a wonderful collection of pictures, some of which I have. The wealth and magnificence of the cedars in the Himalayas is beyond description: the measurement of some is recorded by J. S. Gamble, who says of the deodar that it is the principal timber tree of the Himalayas, and quotes Thomson ("W. Him. and Tibet"), who mentions:

"One near Nachar on the Sutlej that had 35½ ft. in girth. Brandis mentions trees in Kunawar that had 30 to 36 ft. in girth; Dr. Stewart measued one at Kuarsi, in the valley of the Ravi, that was 44 ft. at 2 ft. and 36 ft. at 6 ft. from the ground, and another was ascertained to be 34½ ft. in girth, and to be about 900 years old. Minniken records a tree at Punang in Bashahr that was 150 ft. high, and had a girth of over 36 ft., the clean bole height being 45 ft. The great section in the corridor of the Imperial Forest School at Dehra Dun shows 23 ft. in girth and 665 annual rings, equivalent to about 13 rings per inch of radius; it came from the Gokul Forest in Tehri-Garhwal, and was cut by Mr. E. M. Moir. In the Moriru Forest in the Tehri-Garhwal Leased Forests, I measured in 1898 a stump—or rather shell, for the interior had decayed—that was 34 ft. in girth; while not far off, in Dumrali Block, a dry fallen tree was unearthed, 90 ft. long, and over 7 ft. in diameter at base. It had been dead for at least 100 years, and was, when it fell, probably 550 years old. . . . Aitchison mentions a tree in the Kuram Forests 22 ft. in girth and 150 ft. high. Schlich found a tree in the Sutlej Valley 240 ft. high; and W. R. Fisher tells me he saw one of 216 ft. in the Bashahr forests of the Pabar Valley."

From earliest times history continues to emphasize the high value placed on the tree and the wood of the cedar of Lebanon which the writings of the Greeks and Romans have handed down to posterity. The beauty of the tree is referred to over and over again in verse and prose, while the usefulness and durability, and the chemical properties, are emphasized. It is curious to notice that in spite of what was within our knowledge and that we have been familiar with the tree in Great Britain for three hundred years, the former of these qualities has been only partially recognized, while the latter has been entirely ignored.

The wood forms a good medium for decorative furniture and panelling. The preference shown by architects and principals unfortunately excludes twisted grain and sound knots, which being admitted give admirable character and variety to the finished work. The trees imported from North Africa and India contain less knots and twisted grain, thus producing a larger proportion of clean boards. All three varieties mixed show no apparent difference and are equally aromatic and durable.

The cedars in the Apothecaries Garden, referred to earlier, were made use of for the manufacture of three chairs for the use of the master and wardens of the Apothecaries Company, and are still in regular use. They were exhibited at the Empire Timber Exhibition at Holland Park in 1920, and were greatly admired by all who saw them.

The Rev. C. A. Johns says:

"the value of the timber of the Cedar, as a building material, is now thought to have been over-rated by the ancients. It is reddish white, with streaks, and does not seem to be much harder than deal. It is sweet-scented only for the first year after its being felled: it soon begins to shrink and warp, and is said to be by no means durable. But

this is rather the character of English-grown Cedar than of timber which has come to maturity in its native mountains."

I do not find that I often differ from Johns, but in this case I am afraid that he is quite wrong. The quality and durability of English-grown cedar is in every way as good as that produced elsewhere, and the aromatic scent is persistent—undeniable facts which can be proved.

The forests of cedars on Mt. Lebanon, which were known to the civilized world nearly two thousand years ago, have gone. The Rev. C. A. Johns, in 1849, quotes Maundrell as follows, who measured the largest cedar on Mt. Libanus:

"I found it 12 yards 6 inches in girth and yet sound, and 37 yards in the spread of its boughs."

To-day the traveller would have difficulty in counting a score still remaining. This is a terrible illustration of the destruction of forests with the march of civilization. From every quarter of the globe, whichever way we turn, we are confronted with the same story.

Dr. Fosdick, in a book entitled "A Pilgrimage to Palestine", says, speaking of the country between Samaria and Galilee, and the Plain of Sharon by the sea:

"Whether or not there used to be more trees upon these hills than now has often been discussed, but I do not see how anyone can doubt it. In this last war alone (1914–1918) it is estimated that 40 per cent of all the olive trees in Palestine were cut down for military purposes. To say nothing of the locusts, two great enemies of the trees have ravaged the land for centuries—Militarists and goats. . . . When Pompey came to take Palestine for Rome, the record says that he cleared away the trees, and Josephus tells us that Titus cut down every tree within ten miles of Jerusalem. . . . Even in the Lebanons they are finding boundary stones set by Hadrian's foresters—I saw one in Beirut—where to-day only bare mountains remain. The forest of Hereth, where David hid, is gone; there is no forest of Bethal to shelter bears to-day; Kiriath-jearim, which means 'city of forests', would have no excuse now for such a name, and the woods of Sharon, which Strabo called 'a great forest', and which once stretched from the valley of Ajalon up to Mount Carmel, now have few relics of their ancient glory."

We should indeed be a decadent people if we allowed a thing of such beauty and interest as the cedar tree to vanish from our landscape.

ANTIBACTERIAL SUBSTANCES IN GREEN PLANTS

FROM the earliest times, writes E. M. Osborn (*Brit. J. Exp. Path.*, 24, 227; 1943), plants have been used in the attempt to cure disease. After giving a brief summary of recent work on the well-known occurrence of antibacterial substances in green plants, he records the results of his own investigation of about 2,300 different green plants, most of them flowering plants. All the plants used were freshly picked and all available parts of them were tested. The method of testing used was the diffusion method of Abraham and other Oxford workers (*The Lancet*, ii, 177; 1941), the antibacterial substance being tested against *Staphylococcus aureus* and *Bacterium coli*. The test shows only the presence or absence of the antibacterial substance and is not quantitative. A negative result does not necessarily prove the absence of the antibacterial substances, and the possibility of their destruction by enzymes must also be remembered.

At the time when this paper was written, antibacterial substances had been found in sixty-three genera of plants belonging to twenty-eight families. Extracts from plants belonging to the same families tend to show similar specificity and potency. Inhibiting substances are distributed throughout some plants (for example, *Asarum europæum* (Asarabacca)). In others their distribution is restricted. There is more of them in the seeds of *Brassica oleracea* (cabbage) than in other parts of this plant, and they were found only in the bark of *Magnolia acuminata*. This restricted distribution, together with differences in method of testing, may account for some negative results obtained with plants from which other workers have obtained bactericidal effects (for example, *Chelidonium majus* (greater celandine) and the turnip and horse radish). In many plants the inhibitory substances are produced by enzyme action; for example, *Plumeria bicolor*, *Cheiranthus cheiri* (wallflower) and *Crepis taraxacifolia* (hawk's-beard). In some instances the inhibitory substance is produced by the action of an enzyme situated in one part of the plant on an inactive precursor situated in another part of it. The drying of some plants causes loss of inhibitory power, for example, Clematis, Anemone, Ranunculus; but the drying of others does not (for example, *Crepis taraxacifolia* (hawk's-beard), *Reseda lutea* (wild mignonette) and *Asarum europæum*). Certain well-known drug plants (Atropa, Datura, Digitalis) show no inhibitory power against the organisms used, nor do many plants recommended by herbalists.

A table shows the species from which "frankly positive" results were obtained. A feature of it is the activity of the Ranunculaceæ tested, some of which (for example, Anemone, Clematis, Helleborus and Ranunculus) inhibit both *S. aureus* and *Bact. coli*. Extracts of some plants inhibit only *S. aureus*. Two of the plants tested were specific against *Bact. coli*. A full list of the species tested and the results obtained may be obtained from the Sir William Dunn School of Experimental Pathology, Oxford, and a similar list has been deposited in the archives of the Royal Society at Burlington House, London.

FREQUENCY PERFORMANCE OF QUARTZ PLATES

AN article by W. P. Mason (*Bell Lab. Rec.*, 22, No. 6; February 1944) discloses some of the results of researches carried out to determine the frequency performance of quartz plates cut and oriented in a variety of ways. The natural frequencies depend largely on the plate dimensions and orientation with respect to the faces and angles of the original crystal, and on temperature.

Rectangular co-ordinates x, y, z, were used for specifying the manner of cutting. The z, or optical axis, runs vertically up the centre of the hexagonal prism assumed by the crystal; the y, or mechanical, axis is taken perpendicular to any one of the three pairs of opposite faces; and the x, or electrical, axis runs horizontally through opposite edges of the crystal. The first crystals used were known as x-cut and y-cut. Both have their width parallel to the

z-axis, but the x-cut has its face perpendicular to the x-axis and its length parallel to the y-axis, while the y-cut has its face perpendicular to the y-axis, and its length parallel to the x-axis. For the x-cut crystal the voltage is applied along the electrical axis, and the vibration occurs parallel to the mechanical axis; the frequency is a function chiefly of the crystal length. For the y-cut crystal, the voltage is applied along the mechanical axis; voltages appear along this axis when the applied pressure is at 45° to the mechanical and electrical axes, and thus, when voltage is applied along the y-axis, the vibration is one of shear.

The factors that make it desirable to seek other forms of cuts may be illustrated with the x-cut crystal in which, when voltage is applied along the electrical axis, the vibration is along the mechanical axis. Motion along the electrical axis also gives a displacement of charge along the electrical axis, and thus the x-cut crystal could vibrate in either direction; but the vibration frequency, which will be determined chiefly by the dimension of the crystal in the direction of its vibration, will be much lower when the vibration is along the y-axis than when it is along the x-axis. As used, a voltage frequency was applied corresponding to the length vibration, and thus was comparatively low. If an effort were made to use the crystal for a high frequency, utilizing vibration along the x-axis, difficulties would occur because harmonics of the y-axis frequency might be very close to the x-axis frequency, and slight changes in conditions might cause the controlling vibration to shift from that of the x-frequency to a harmonic of a y-frequency.

The most common of such changes of conditions is the temperature, since the frequency of the x-cut crystal, and of the y-cut, is very sensitive to temperature changes. With a crystal of zero temperature coefficient, the frequency can be held to almost negligible variations by maintaining the crystal at the proper temperature. Accurate temperature control apparatus, however, is necessary when high constancy of frequency is desired. It would be very desirable if a crystal cut were available that had a zero temperature coefficient over a wide range of temperature, since this would make temperature control unnecessary over this range. Search for such a cut resulted in a crystal having a temperature coefficient essentially zero from 0° to 100° C. The various cuts, besides giving the temperature characteristics desired, are also selected, and the dimensions of the crystal chosen, so that there will be only one mode of vibration of fundamental or harmonic frequency in the neighbourhood of the frequency at which the crystal is to be operated.

THE 'MICROTIMER'

AN electronic timing device called the 'Microtimer' has been produced by R. K. Dundas, Ltd., The Airport, Portsmouth. This measures the time interval between the making, or alternatively, the breaking, of two electrical contacts, or between any other combination of contacts. In addition it may be operated, without contacts, by a suitable valve amplifier in conjunction with, for example, a photo-electric cell. The time indication is given by the position of a pointer moving over the dial of a meter, and the standard instrument has ranges covering 10 to 1,000 milliseconds for full-scale deflexion. It operates entirely from the standard A.C. mains, although a battery model is available. Tests show that the instrument has negligible zero drift, is simple to calibrate and use and is of rugged construction. After taking a measurement, the deflexion of the meter is maintained for several minutes without appreciable drift; throwing a switch brings the meter back to zero for the next measurement. The accuracy claimed is within ± 2 per cent of the full scale deflexion on any range, even allowing for violent changes in mains voltage or changes of the valves.

The principle of the circuit, which incorporates patented features, may be briefly described. A condenser is charged up from the high-tension supply, and at the beginning of the interval to be timed, the energy in this condenser is allowed to flow through a constant-current pentode valve into a precision condenser. At the end of the timed interval this current is stopped, and the voltage which has been built up across the precision condenser is measured by means of a high-impedance valve voltmeter, to which the output meter is connected, this meter being, of course, calibrated in milliseconds. A voltage stabilizer in the high-tension supply and the provision of considerable negative-feedback assist in maintaining the accuracy of calibration and freedom from drift.

The 'Microtimer', although designed as a laboratory instrument, may be readily operated in routine work by unskilled personnel, and may have a large variety of applications, such as timing the operation of relays, switches, fuses, contact breakers, camera shutters and automatic machinery of all kinds, and in radio, physical and explosives research.

FORTHCOMING EVENTS

Monday, May 15

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at Lincoln's Inn Fields, London, W.C.2), at 4 p.m.—Prof. John Beattie: "Clinical Aspects of Methionine Metabolism".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Dr. Olaf Devik: "The Formation of Ice in Lakes and Rivers".

INSTITUTION OF ELECTRICAL ENGINEERS (LONDON STUDENTS' SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 7 p.m.—Annual General Meeting.

Tuesday, May 16

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Lieut. Bernard Mishkin: "The Indians of the Andes".

Wednesday, May 17

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Scientific Papers.

ROYAL COLLEGE OF SURGEONS OF ENGLAND (at Lincoln's Inn Fields, London, W.C.2), at 4 p.m.—Prof. John Beattie: "Clinical Aspects of Methionine Metabolism".

ZOOLOGICAL SOCIETY OF LONDON (at Regent's Park, London, N.W.8), at 4.30 p.m.—Exhibition of a Soviet Film on "Animal Life in the Kara-Kum Desert", with commentary by Dr. Edward Hindle, F.R.S.; Dr. Ruth Deansley: Demonstration of the Breeding Habits and Life-cycle of *Xenopus*; Mr G. P. Wells: "The Parapodia of *Arenicola marina* L. (Polychæta)".

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. R. B. Armstrong and Mr. J. A. Smale: "High Speed Recording of Radio-Telegraph Signals".

INSTITUTE OF WELDING (joint meeting with the INSTITUTE OF THE PLASTICS INDUSTRY) (at the Institution of Civil Engineers, Great George Street, Westminster, London, S.W.1), at 6 p.m.—Dr. J. H. Paterson: "The Welding of Plastics".

BRITISH INSTITUTION OF RADIO ENGINEERS (MIDLAND SECTION) (at the University (Latin Theatre), Edmund Street, Birmingham), at 6.30 p.m.—Dr. Emrys Williams: "Relaxation Oscillators and Trigger Circuits".

Thursday, May 18

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. H. C. Waite: "African Art".

ELECTRICAL ASSOCIATION FOR WOMEN (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 2 p.m.—Annual General Meeting.

SOCIETY OF CHEMICAL INDUSTRY (joint meeting of the PLASTICS GROUP and the BIRMINGHAM AND MIDLAND SECTION) (at the Chamber of Commerce, New Street, Birmingham), at 2.30 p.m.—Dr. J. Hofton: "Amino Resins".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Dr. F. G. Mann "Some Aspects of the Organic Chemistry of Phosphorus and Arsenic" (Tilden Lecture).

INSTITUTE OF FUEL (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr R. H. Anderson, Mr. D. C. Gunn and Dr. A. L. Roberts: "Uses of Permeable Refractories for Furnace Construction".

Friday, May 19

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 4.30 p.m.—Dr. H. S. Souttar: "Team Work in the Treatment of Cancer" (Twenty-first Mackenzie Davidson Memorial Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS (MEASUREMENTS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5 30 p.m.—Dr. L. Hartshorn: "Foundations of Electrical Measurements".

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Prof. G. V. Lomonossoff and Capt. G. Lomonossoff: "Condensing Locomotives".

Saturday, May 20

NUTRITION SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 10.50 a.m.—Conference on "Budgetary and Dietary Surveys of Families and Individuals", Part 2 (to be opened by Prof. V. H. Mottram, Mrs. Barbara Callow, Dr. C. P. Stewart and Miss M. C. Broatch).

BRITISH INSTITUTE OF RADIOLOGY (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 2 30 p.m.—Annual General Meeting; at 3.15 p.m.—Prof. S. Russ: "The Man Silvanus Thompson" (Twenty-third Silvanus Thompson Memorial Lecture).

INSTITUTE OF PHYSICS (joint meeting of the INDUSTRIAL RADIOLOGY GROUP and the MANCHESTER AND DISTRICT BRANCH) (in the Physics Department, The University, Manchester), at 2.30 p.m.—Mr. C. T. Snushall: "Filters and Intensifying Screens—their Applications in Light-Alloy Radiography".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

GRADUATE ASSISTANT MISTRESS to teach CHEMISTRY and PHYSICS to School Certificate and Higher School Certificate standard, at the Plymouth High School for Girls, and an ASSISTANT MASTER qualified to teach PRACTICAL PLANE AND SOLID GEOMETRY for Engineering and Building Courses, at the Plymouth Junior Technical School for Boys—The Director of Education, Education Offices, Cobourg Street, Plymouth (May 18).

EDUCATIONAL PSYCHOLOGIST (man or woman)—The Director of Education, Education Department, Town Hall, Crouch End, London, N.8 (May 20).

TEACHERS (with Graduate or equivalent qualifications) IN ENGINEERING AND BUILDING SCIENCE, ENGINEERING WORKSHOP SUBJECTS and TECHNICAL DRAWING (Engineering and Building), at the Wolverhampton Technical High School—The Director of Education, Education Offices, Wolverhampton (May 20).

LECTURER IN BIOLOGY (to give assistance with Chemistry), and a LECTURER IN CHEMISTRY (to give assistance with Biology or Physics), at the Hull Municipal Technical College—The Director of Education, Guildhall, Hull (May 20).

BACTERIOLOGIST for research work in connexion with Bovine Mastitis—The Secretary, Hannah Dairy Research Institute, Kirkhill, Ayr (May 20).

ASSISTANT to teach ENGINEERING DRAWING, MATHEMATICS, and ENGINEERING SCIENCE, at the Jarrow Technical School—The Director of Education, Shire Hall, Durham (May 22).

ASSISTANT ENGINEER for the Northern Rhodesia Government Public Works Department—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.697A) (May 24).

LECTURER IN CHEMISTRY—The Acting Secretary of University Court, The University, Glasgow (May 26).

TEACHER OF BOTANY in the Science Department, to take classes up to General Degree standard—The Clerk to the Governors, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17 (May 27).

ASSISTANT LECTURER AND DEMONSTRATOR (woman) IN CHEMISTRY—The Principal, Royal Holloway College, Englefield Green, Surrey (May 31).

ASSISTANT MASTER (with Graduate or equivalent professional qualifications) to teach MATHEMATICS AND GENERAL SCIENCE at the Scarborough Technical Institute—The Secretary, Education Offices, County Hall, Northallerton (June 3).

STAFF LECTURER IN SCIENCE AND HYGIENE—The Principal, Northern Counties Training College of Cookery and Domestic Science, at Tower House, Tweedmouth, Berwick-upon-Tweed (June 10).

HENRY MECHAN CHAIR OF PUBLIC HEALTH—The Acting Secretary of University Court, The University, Glasgow (June 15).

METALLURGIST by Firm of Engineers with wide interests (Ph.D., or equivalent, minimum technical qualification)—The Ministry of Labour and National Service, Room 432, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.2286XA) (June 17).

JOHN RANKIN CHAIR OF GEOGRAPHY—The Registrar, The University, Liverpool (July 31).

W. H. COLLINS PROFESSORSHIP OF HUMAN AND COMPARATIVE PATHOLOGY—The Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W C 2 (July 31).

SENIOR LECTURESHIP IN THE DEPARTMENT OF METALLURGY of the University of the Witwatersrand—Dr. W. Cullen, 4 Broad Street Place, London, E.C 2 (July 31).

ARC WELDING ELECTRODE PRODUCTION ENGINEER, with experience of solid extrusions, to take charge of latest type manufacturing plant—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting Reference No. O.N.Q S 178).

LECTURER IN BACTERIOLOGY to students preparing for the National Diploma in Dairying—The Principal, Studley Agricultural College for Women, Studley, Warwickshire.

LABORATORY TECHNICIAN (male) holding the Certificate in Bacteriology of the Institute of Medical Laboratory Technicians—The Director of the Clinical Laboratory, Royal Infirmary, Manchester.

ASSISTANT MASTER FOR ENGINEERING SUBJECTS, at the Burton-upon-Trent Technical Institute—The Secretary and Director of Education, Education Offices, Guild Street, Burton-upon-Trent.

WELDING ENGINEER by a Steel and Engineering Firm in the North-East, to initiate and develop fabrication of steel forgings and castings of heaviest types—The Ministry of Labour and National Service, Appointments Office, 38 Great North Road, Newcastle-upon-Tyne (quoting Reference No. 397).

SENIOR STRUCTURAL DESIGNER (Reference No. O.S.86), and a CHIEF MECHANICAL DESIGNER (Reference No. O.S.87), by a large Firm of Structural and Mechanical Engineers in India—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting the appropriate Reference No.).

ASSISTANT (male) IN BIOCHEMISTRY at the Courtauld Institute of Biochemistry—The Medical School Secretary, Middlesex Hospital, London, W.1.

RECRUITMENT AND TRAINING OF TEACHERS

PRIMARY AND SECONDARY SCHOOL TEACHERS

WHEN the president of the Board of Education presented the now famous White Paper in July of last year, he made some reference to the coming need of a teaching profession which should be adequate, both in numbers and in quality, to a radically reformed system of education. At that time he found it inconvenient to say much more on the subject, except that there were "some things so patently wrong with the present system that an expert inquiry is long overdue". Again, the Bill which five months later followed the White Paper made no explicit reference to teachers, except that which achieved notoriety as Clause 82. In every other sense the turn of the teachers to stand in the limelight was still to come. So far back as March 1942, Mr. Butler appointed a committee, with Dr. (now Sir) Arnold McNair as chairman, "to investigate the present sources of supply and the methods of recruitment and training of teachers and youth leaders and to report what principles should guide the Board in these matters in the future". The long —and perhaps rather impatiently—awaited report has now been published, and will be known as the McNair Report. The delay is partly due to the appearance meantime of the White Paper and of the Norwood Report, but partly also, there is little doubt, to a difference of opinion which, so far from resulting in a mere minority report, split the Committee into two precisely equal groups.

The report is divided into four parts. Part 1 deals with teachers in primary and secondary schools and with the organization of training generally, Part 2 deals with youth leaders and teachers in young people's colleges, and Part 3 with teachers in technical colleges and schools. In Part 4 the special needs of Wales and some other important matters are considered. In the present article, we deal mainly with the problems raised in Part 1.

The magnitude of the problem of supply is familiar enough to experienced administrators, but for the general public it is best explained by a few figures. It is estimated that when the reforms proposed in the Education Bill are in full swing, the army of teachers required will be no less than a quarter of a million. Assuming that the present rate of wastage in the teaching profession will continue, primary and secondary schools alone will need an annual intake of at least 15,000 new teachers. So much for the coming need. On the other hand, we know that in the years immediately preceding the outbreak of war, the annual output of the existing training colleges and university training departments was less than 7,000. The cold figures are impressive enough, but they are by no means all. There never has been a clearly defined objective and a settled policy in Great Britain as to the supply and training of teachers, so that even before the War there was severe criticism of the recruitment of teachers, the institutions in

which many of them were trained, and the conditions of their subsequent service. Yet it is admitted on all hands, and proclaimed in no uncertain voice by the President of the Board, that the really educated democracy contemplated in the Education Bill can never be achieved unless the educational system is manned by a teaching profession adequate in numbers, carefully selected, and well trained.

At present, the avenue to the training college or department lies through the upper forms of the secondary, that is, the grammar schools, a source of supply which will now become quite inadequate. In order to obtain the required number of entrants of the quality desired, the Committee makes numerous suggestions which we can only summarize briefly. The field of recruitment, it says, should be widened to include boys and girls from senior (modern) schools and junior technical schools who may be suitable. More children in the grammar schools should be encouraged to consider teaching as a profession. The transfer to teaching of persons of maturer age from other professions should be made possible. Maintenance allowances should be given in addition to family allowances to enable children to stay at school until they are eighteen, and in modern schools sixth forms or their equivalent should be developed to provide pupils between sixteen and eighteen with an education which will qualify them for admission to a training college or a university. All types of secondary schools should see that the claims, conditions and prospects of the teaching profession are adequately presented to their older children. The fact that bad buildings and large classes are the greatest deterrent to recruitment should be realized. The marriage bar should be removed. The rules which prevent teachers from playing a part in public life should be relaxed, and schools should be so staffed that the presence of all teachers all the time should not be regarded as a necessary condition of effective work. Special arrangements should be made to meet the needs of married women, and the use of part-time teachers should be encouraged. The esteem in which the education service is held should be improved, so that it may become attractive to intelligent and cultured men and women. High public esteem being an obvious factor in recruitment, parents and others should be given the opportunity of learning about the new educational system.

The foregoing summary statement, every item of which is fully elaborated in the report, is enough to illustrate the painstaking thoroughness with which the Committee has handled this essential part of its work. But as the reader turns the pages devoted to these excellent suggestions, there inevitably lurks in his mind the difficulties of persons who may feel attracted to the teaching profession, but who under present arrangements simply cannot afford to yield to the attraction, and therefore seek other openings. A missionary spirit, the Committee reminds us, cannot be relied upon to maintain the supply and the morale of a quarter of a million teachers. "Teaching is indeed a form of social service, but like other professions it is also a bread and butter affair." A comparison is drawn between the salaries earned by teachers and by Civil servants of comparable grades. It is found that in a large provincial town a certificated teacher has a maximum, after allowing for pension deductions, which is £162 less than the maximum salary of a junior executive officer in the Civil Service, in spite of the extra years spent in a training college or university. The Committee recommends a substantial increase in the salaries of teachers, the present scales being often insufficient for personal needs and family responsibilities, and therefore inadequate to attract teachers of the quality and quantity required. It holds also that the present scales differentiate unfairly between elementary and secondary schools. It recommends a single basic scale for all teachers in primary and secondary schools, with additions for special qualifications or special responsibilities. The Committee's final word on the subject will often be quoted: "we have not yet emancipated ourselves from the tradition of educating our children on the cheap".

The Committee takes the bold course of recommending the abolition of the time-honoured distinction, applicable only to elementary school teachers, between the certificated and the uncertificated. Instead, the Board should recognize only one grade of teacher in both primary and secondary schools, the "qualified teacher", that is, normally one who has satisfactorily completed an approved course of education and training. The normal course in training colleges should be extended from two to three years, with one term of continuous practice in a selected school. An essential element at this stage, the report wisely adds, is a reasonable amount of leisure and a personal choice in the use of it. There should be an accessible college or centre devoting special attention to the education and training of teachers of art and crafts, music, physical education and domestic subjects. The same kind of facility should be provided for students desiring to take part of their training in an institution in a rural area. Training facilities should also be within reach of teachers preparing to take up work with young children and with handicapped children in special schools.

We now come to the big problem of general organization. The Committee agrees that the Board of Education should now assume the obligation of ensuring that training institutions adequate in number and quality are available, and are fused into a national system. We may remark, incidentally, that such an obligation rests upon the Board in respect of schools, but that in respect of training colleges it is an entirely new thing. To secure this end, the Committee considers that two constitutional changes are necessary: (1) the formation by the President of the Board of a small central training council, and (2) the close integration of all training institutions and interests on a convenient area basis.

Thus far the Committee is unanimous; but at this point it splits into the two equal groups to which we have referred. It is divided in opinion as to the areas. It may be useful here to explain that fifteen years ago a very important change was made in the examination of students in training colleges

and the consequent award of certificates. Up to that time, the examination had been conducted by the Board of Education, preceded by the old Education Department. It was widely held to be an out-of-date arrangement that had come down from the time of Kay-Shuttleworth. Indeed, one important exception had already been made, by which a training college, the largest in England, opened in 1905, and owned and controlled by a university, was never examined by the Board, but by the university—the Board, of course, having the final word as the awarder of its certificates. By the change made fifteen years ago, this arrangement was generalized. The universities (with the exception of Oxford), at the request of the Board of Education, took over the responsibility for the testing and examination of students. Each university, and the training colleges more or less grouped round it, formed a Joint Board, responsible for the appointment of external examiners and for the conduct of examinations. We may remark in passing that the examination for the teacher's certificate thus became partly internal instead of purely external. The Joint Boards thus constituted exist to this day. Five members of the Committee recommend that the Joint Boards should be abolished, and that each university should establish a "University School of Education", to which training colleges should be affiliated. The other five recommend that the Joint Board scheme, instead of being abolished, should be developed and strengthened.

Obviously the main difference between the two schemes lies in the part which should be played by the universities in the training of teachers. To say, at once, as *The Times* has said, that there "appears little doubt" that the scheme which makes the universities responsible is preferable is, we suggest, scarcely to do justice to the case presented by the other side. If the Joint Boards have "failed to promote real co-ordination, except in the matter of examinations", it must be remembered, not only that the reform of the examination system was the reason for their creation, but also that the universities, as the predominant partners, must bear most of the blame for the alleged failure to utilize a great opportunity. The five advocates of the Joint Board scheme appear to us to be quite as keenly aware as their five colleagues of the shortcomings of the existing Joint Boards, and what they really advocate amounts almost to a new scheme under the old name. No one should make up his mind on the subject without carefully weighing their arguments. On the face of it, the President of the Board is now asked to adopt one scheme and set aside the other. He will have many counsellors to consider besides the ten members of the McNair Committee, and it would not surprise us if, with his genius for compromise, he devises a plan which, while not placing responsibility at once upon the universities, would be a possible step in that direction. Fifteen years ago, as many will remember, the universities had thrust upon them a responsibility which most of them did not by any means desire. The promise of a successful enterprise was not there from the first. It remains to be seen how far they are convinced by the case for university responsibility put forward by one half of this Committee.

Many other points in the report deserve more comment than can be made here. The system under which earmarked grants are made to students who sign a declaration or 'pledge' that they intend to become teachers is condemned. So also is the system of loans to students—another form of bribery to enter an ill-rewarded profession. Again, the conditions in many training colleges are reported as needing drastic improvement. Nearly two thousand students in training colleges sleep in cubicles rather than in bedrooms or study-bedrooms. In some cases the training colleges impose discipline on their students which is obsolete and unsuitable. Unless, adds the Committee, students are allowed more freedom, they cannot be expected to acquire that sense of responsibility essential to teachers.

One further matter calls for special comment. We refer to the strong line taken by the Committee in the matter of speech training. Unless, the Committee says, a teacher has at least a moderate competence in reading, writing, speaking and listening, he is hampered at every turn. We agree, and we must add that thereby hangs a tale. So long as the Education Department or Board of Education conducted the examinations, every outgoing student in a training college stood up and read or recited to the inspector, during his annual visit, and he was trained to meet this ordeal. When the Board ceased to examine, this salutary practice also ceased. Again, when the secondary school became the normal avenue of access to the training college, the change from the old pupil-teacher system, though entirely admirable in every other way, did no good to the cause of clear speech in the training college, for reasons which the Norwood Report has made abundantly clear. One can therefore quite understand that the position in training colleges on this vital matter has gone steadily from bad to worse. Is it too much to say that the ultimate responsibility for this sad deterioration lies with the universities, where the finest of scholars are sometimes the worst of speakers and therefore the worst of lecturers, and are thought none the less efficient on that account? Teachers and preachers and actors and politicians, all maybe educated at universities, have had to rely upon their natural gift of speech, which may be good or bad or indifferent. So far as teachers are concerned, the recommendation of the McNair Report is clear and emphatic. It recommends "that the Board of Education should require every training institution to pay attention to the speech of every student, and every area training authority to include in the assessment of a student's practical teaching the ability to use the English language". It further recommends "that the Board of Education should require every training institution to make arrangements for the detection of speech disabilities and for the provision of speech-therapy and training where necessary". This call for assistance from a new but ably cultivated branch of science will not go unanswered; and nothing but beneficial effects will be achieved.

RACIAL DISCRIMINATION

Man's Most Dangerous Myth

The Fallacy of Race. By M. F. Ashley Montagu. Pp. xii+216. (New York: Columbia University Press; London: Oxford University Press, 1942.) 15*s*. 6*d*. net.

THE author's thesis is that experience rather than inborn traits determines standards of social conduct, that most so-called lower-grade human types would reach high standards in this respect if given opportunities, that we must not assume standards other than our own to be necessarily inferior but must allow that adaptations in diverse environments give rise to different standards, and that outbreeding promotes vigour. He therefore condemns racial discrimination, especially in the U.S.A., and urges a policy of social amelioration and education, looking to the lowering of racial barriers and to implementing the first principle of the American Declaration of Independence. Race discrimination has, in any event, failed to prevent widespread mixture. He sees the human individual as the developed result of a bundle of genes of many origins, the bundle re-sorting itself in the development of every child. He might perhaps have gone further in this direction by acknowledging that *genes* are hypothetical, even though the gene hypothesis has more in it than the race hypothesis.

The race hypothesis, as commonly put forward, presupposes the segregation of parts of an original human group into separate groups with divergent modifications. It then makes a classification on the basis of skin colour and hair texture, and lumps together all the people with dark skins and kinky hair as though they had branched off from the rest of humanity as a unit and had had a subsequent history of their own. But even Ashley Montagu scarcely sees how improbable that racist view is. Archæology tells us of drifts of men at various very early times in various directions into Western Europe, East and South Africa, India and the East Indies and so on. We seem to find cranial characteristics, which were common, but not universal, among men of certain phases of the Old Stone Age, now exhibited among people from various remote areas in Europe, Africa, and south-east Asia and Australia. But the people who show these cranial characters are white, yellow-brown, dark brown or almost black and have wavy hair or kinky hair, all largely according to the region they inhabit. One must have regard to hypotheses that race drifts with diverse cranial characters, and also social standards, spreading in Europe, Asia and Africa, nearly all have regional characters of pigmentation and hair texture impressed on them. This strongly suggests that the idea of *one* African race with a mainly separate history from its inception is artificial in the extreme; as indeed, Ashley Montagu says, all systems of racial classification must be. Different characteristics have different kinds of histories, mostly still very imperfectly understood, but it is a first step to better understanding to realize that the growth of our physical features is the result of a combination of innate and environmental influences that are tangled up beyond possibility of separation; and that we cannot consider an individual as one unit of inheritance—we are all gatherings of fragments.

Why is it that race prejudice is so powerful? We are typically concerned to maintain our social standards, most of all perhaps to see that our daughters do not drop to lower social grades when they marry. Now the assessment of social grade is a complex affair; but, when, as in the southern parts of the United States, the lower grades are often those made up largely of coloured people, it becomes easy to transfer the prejudice from 'low grade' to 'coloured', and analogous transfer has occurred in the case of the Jews of Central Europe on the basis of other physical characters, among the Bantu of South Africa and many another group. The facts that it has not occurred appreciably among the Maori and that it is less marked in Latin- than in English-speaking America are of outstanding importance, and are to be accounted for on very different lines in these two cases.

We know very well in this twentieth century that several of the outstanding personalities of the world have other than white skins, even though it has been the white-skinned people who have on the whole set the general standard in the nineteenth century by which distinction is reckoned. The white man owes his superiority largely to his invention of devices for mechanical power in industry and to his development of medical science. Whether that standard will survive, with the spread of machinery to Asia and Africa, and the crisis of reproductivity that is so widespread in north-west Europe, remains to be seen.

In any event, it is becoming not only wrong but also excessively stupid to hold men down to menial positions and to subject them to indignities because of skin-colour. We can all think instantly of individual after individual whose value to humanity forces respect even from the prejudiced white man, and who carries the scars of past and sometimes present ostracism. Ashley Montagu points out how harmful this is to both the coloured man and the white, and pleads for education, accompanying a real recognition of membership of humanity, and a forthright condemnation of the racism of Henry Fairfield Osborn, Madison Grant, Houston Stewart Chamberlain, and the Nazis in Europe. There is no evidence for general physiological harmfulness of inter-marriage of people with very diverse physical characters; there is only too much evidence of the social danger of inter-marriage between people of very diverse upbringing and social standards. It is true that very occasionally a physical heritage for one parent does not fit an adjacent heritage from the other parent; but this occurs in children of parents who belong to the same nation as well as in children who would commonly be considered to be of more hybrid make-up. In both it is a rare phenomenon.

Some mixtures also are probably very valuable if given a fair opportunity; it is, for example, said by some observers that Anglo-Chinese children tend to be very intelligent, while the vigour in several respects of the French Canadians with their tincture of indigenous American heritage has often been mentioned.

It is obvious that, with the best of intentions, we may use our influence and prestige unwisely if we seek to transplant our whole system among peoples of quite different experience. The British educational effort in India was for generations far too literary and so not able to touch the masses, besides producing disaffection among those who got a smattering of it. The idea of implanting a fully developed parliamentary system among peoples who have little tradition in that direction is another obvious source of trouble. The problems of inter-racial contacts are,

in fact, insoluble save by the softening influence of more contact, and by the wider recognition of our common humanity and of the white man's weaknesses as well as of his power to help. Consciousness of supposed superiority on one side and of impressed inferiority on the other are the bane of all relations between peoples of diverse traditions.

IS THE MIND A CALCULATING MACHINE?

The Nature of Explanation

By Dr. K. J. W. Craik. Pp. viii+124. (Cambridge: At the University Press, 1943.) 6s. net.

AT a time when professional philosophers are trying to persuade us that philosophy is an attempt to answer questions which should never have been asked, and professional scientists are taking over the task of answering the questions, it is refreshing to come upon a writer on philosophy who, after a few preliminary skirmishes with the modern sceptics, unhesitatingly attacks a philosophical problem by the plain scientific method. Dr. Craik makes his philosophical point of view crystal clear. He believes in the methods of the observational scientists as the only methods of explanation. He is intolerant only of those who will not experiment and who consider that the virtue of thought is analytic precision rather than fruitfulness in the experimental field. He confesses that he has no gift for analytic precision and is particularly addicted to confusing similar concepts. He is, quite clearly, not deeply versed in traditional philosophy. This gives his book a certain freshness of outlook, although it makes his criticisms of the great philosophers, particularly Kant, appear rather naïve.

The first three chapters discuss five attitudes in which one might approach the question, "What is explanation?": (1) The *a priori* method consists in the logical deduction of conclusions from premises accepted as indubitable because the terms involved have been clearly and precisely defined. When coupled with empiricism, as sooner or later it must be, apriorism is transformed into (2) scepticism. (3) There is the view that explanation is merely description, which says nothing about causes. (4) There is the relational theory, which also insists that explanation has no interest in causes, its task being to find relations between observable entities. (5) There is finally the causal theory, which holds that explanation consists in discovering the actual interaction of things within the universe.

Although Dr. Craik is not clear on this point, he seems to consider it necessary to disprove the first four theories and to establish the causal theory before he formulates his theory of the nature of explanation. Apriorism is rejected because analytic certainty is an illusion. In attacking scepticism he insists that the assurance of an outer world is to be found not in any proof but in the fact that our symbolism works. The point could have been more convincingly established by showing that all usages of the word 'outer' in English have no relevance to the question "Is there an outer world?", and that in this context 'outer' is meaningless. Dr. Craik, however, in his justifiable hostility to the metaphysics of logical positivism, fails to grasp the importance of its linguistic analysis. Relational and descriptive theories such as those held by modern physicists, which associate definite probabilities with events and eschew any attempt to find an underlying causality, are rejected on the grounds that probability is meaningless without causality. Like symbolism, causality is accepted because it works.

This preliminary discussion paves the way for the main thesis, which can be stated as follows. The nature of thought is essentially prediction. Prediction consists in devising symbols to represent an external process, performing a mental operation upon those symbols, and then translating the result back again into an external situation. Calculating machines, A.A. predictors, do just this sort of thing, because in certain essential respects they parallel the external reality.

This is the hypothesis. The first question that presents itself is, "What corresponds in the mind to the mechanical parts and movements in the predictor or the calculating machine?" One answer, which the author does not consider, is that it is the symbols and the transformations which they undergo in accordance with logical principles. This is a perfectly intelligible view. It was put forward very clearly by the great American philosopher, C. S. Peirce, who states that reasoning consists in performing mental experiments upon symbols. the grouping of the symbols representing the arrangement of the facts so far as is necessary for the reasoning involved. In this connexion Peirce developed a system of logical graphs which in an abstractly pictorial way enable the premises of an argument to be represented and the conclusion read off. Dr. Craik, however, seeks his analogue for the calculating machine in the brain, and suggests that it is to be found in "neural patterns". Implication would then be the power of these neural patterns to act on each other as the real events act causally upon one another. He even suggests that a physiologist, if he could see these patterns in the living brain, might be able to interpret the ideas they represent and, presumably, though this is not stated, to follow the argument. This is difficult doctrine.

In a chapter entitled "Methods of Testing this Hypothesis", experiment with the view of establishing the meaning of words pragmatically is strongly urged; but it is difficult to see what relevance such experiment could have to a hypothesis about the brain. In the last few pages the truth emerges that it is the physiology and biochemistry of the brain that must be used to test the theory, and no experiments are suggested in these spheres.

The book, considered as a reasoned exposition of a single hypothesis, is not wholly successful, because the author has not presented the hypothesis in such a way as to make clear just how it can be confirmed or refuted by experiment. He seems quite unaware, for example, of the enormous leap he makes in the transition from symbols to neural patterns. There is compensation in the number of illuminating suggestions which are struck off like sparks in the course of the argument. There are two or three pages on the ethics of selfishness which are worth a volume of professional moralizing, and a valuable suggestion about the part played by feeling in the formation of hypotheses. Finally, to have an idea is, for Dr. Craik, to think of ways of testing it; and, for many incidental ideas on the fringe of the main argument, he makes ingenious suggestions about establishing or refuting their validity.

WINSTON H. F. BARNES.

EDUCATION AND THE COMMUNITY IN AFRICA

By PROF. DARYLL FORDE
Director, International African Institute

THE discrepancy between technological advance and social adaptation which is reflected in the crises and upheavals of the twentieth century is from many points of view the fundamental problem of our time. Although the economic and social problems of Africa may seem less urgent and menacing than those of Europe, this discordance and the social disequilibrium that accompanies it are, in fact, developing in an extreme form. The very fact that in Africa indigenous techniques and social organization have been comparatively simple means that the gap to be bridged in the process of integration with the Western world is correspondingly great and the social transformation all the more far-reaching. The pace of technological and economic change is quickening every day, and the need to smooth the path of the inevitable transition from small-scale tribal communities to a self-sustaining social organization commensurate with a large-scale exchange economy becomes increasingly urgent. There is perhaps little appreciation that failure may involve at a later stage violent social upheavals and zenophobia on a continental scale. Where the inadequacies of the existing agencies for social development and the evils of socially disintegrative individualism are seen at close quarters by the administrator, the missionary or the educator, the problems are often formulated only in economic or ethical terms and as questions of administrative machinery. The opportunities and needs for guiding the development of the more general social framework to meet the technical and economic changes have hitherto received little consideration. The fact that the effectiveness of such guidance will necessarily depend on the amounts of human energy and resources that are devoted to the reconstruction of the social organization of African communities finds inadequate recognition.

It is little more than a generation since the African villager lived in a small, practically closed society in which status and obligations were determined by a network of local and personal relations. Farming and stock-raising required co-operation only with kinsmen and fellow villagers. Despite occasional and violent incursions from the vague outer world, religious and political concepts were, like economic values, bounded by a universe of a few thousand people. Even where centralized political institutions had created more considerable states, limitations on transport and division of labour left a high degree of autonomy to the local settlement group. The people in these small communities, knit together by a close web of inter-personal relations which guided and restrained their conduct at nearly every point, are all now being progressively affected by the rewards and demands of the world economy, and the regulations of an impersonal Western administration.

The old economic self-sufficiency of African communities is already a thing of the past. Even where direct production for local needs is still considerable, it is the new values associated with cash returns for crops and labour, market purchases of trade-goods, the achievement of new standards in dress and food and opportunities for learning new trades that are dominating the outlook of the energetic and progressive. One of the most significant social aspects of this process is the fact that Africans have so often been brought into the orbit of the outer world not as communities but as individuals. The migrant or permanently urbanized wage-labourer, the villager who sells his crop of maize, ground-nuts or palm oil for the external market, the hawker of cloth and hardware in village markets, and the middleman who buys up produce for the Western firms, all encounter and adapt themselves to the new economic opportunities and Western cultural values as individuals. There is at once a greater freedom for personal initiative in new fields and a weakening of effective control and support of the individual by the community. As the individual secures personal returns in an open market as well as a higher mobility and a widening choice of where and how to live, the old norms begin to lose their validity and the community itself to disintegrate. But new standards and a new social framework are slow to emerge. There is instead a trend towards detribalization into amorphous aggregations shot through with new forms of individual competitiveness that are often restrained only by the external authority of the European administrative system. Unless the new occupations, rewards and demands are linked to social forms which can both ensure group benefits and security and harness individual effort to social ends, the period of adjustment from the old tribal life to a social equilibrium consistent with the new economies will be marred by social conflict, with waste of both human capacities and material resources.

The basic sociological principles underlying satisfactory adaptation to such rapid changes are not recondite. There is in the first place the need for attaching new functions and techniques to existing social structures, which are themselves concurrently adapted so that they do not become functionless and obstructive. By this means, the activities of the more capable and energetic who are in the vanguard of economic change do not become independent of the salutary restraints of group standards, with a significant loss of social solidarity.

Secondly, there is need for the progressive integration of the small-scale groups, appropriate to the earlier less complex economy, into larger and more comprehensive groups. Since the pattern of small groups, with their corporate sense and will to survive, already exists, economic change may easily lead to internecine struggles for dominance among them—struggles which result not only in loss of well-being and security by the unsuccessful but also in a less efficient, because economically less productive, transition to a new social pattern. The problem therefore resolves itself into securing progressively higher levels of group organization to which the loyalties and sense of interest attached to existing small groups is in part transferred. Intensification of faction within communities and jealous rivalry between them are typical social reactions to economic change where there is little grasp of the nature and long-term effects of the forces involved, and they can be reduced only by policies designed to promote understanding of the forces at work, and behaviour that is adjusted to new economic organization. This involves not merely education in the formal sense, but also the enlightening of the adult population and especially the leaders, traditional and newly arrived, concerning the technical and economic conditions of their lives.

These are among the main issues underlying the

recent report on Mass Education in African Society by a Sub-Committee of the Advisory Committee on Education in the Colonies*, which rightly puts the active participation of the community in education proper and also in all projects for social development as the first requirement for satisfactory development under rapidly changing conditions. It comments acutely on a changing attitude towards economic disabilities or misfortunes, noting a growing attitude which tends to exaggerate the direct responsibility of groups or individuals, especially those in authority, for all such happenings. Both the suspicion of economic exploitation and the growth of political aspirations, as well as the often vague but far-reaching sense of participation in a common struggle during the War which confers common rights in the economic and political organization of the future, require constructive measures to avert narrowly nationalistic demands. The report recognizes that the need for combining effective guidance with the evocation of leadership from among the people themselves involves the co-ordination of many diverse agencies, which will, as is shown, prove no easy task. On one hand, members of the administration, education departments, technical services, missions and African churches must be welded into co-operating teams, subordinating their sectional or professional interests and prestige to the common objective of securing the greatest confidence and enlisting the fullest participation of the people themselves. For it is the widened experience and capacity for judgment which such participation can give that an educational programme should seek to provide. Only on such a basis will sustained effort and wise leadership be forthcoming from the African communities themselves. It presupposes, as the report points out, objectives with which the people can readily identify themselves, and while there must be provision for freedom of discussion and criticism, "there must be opportunity for extending the range of knowledge relevant to the changing conditions. Full discussion in itself is valuable, but it is not a substitute for being well informed".

The mass education programme is summed up as an effort to provide this experience and at the same time to "call out the ability and the will to share in the direction and control of the social, economic and political forces" by means of a co-ordinated effort of both official and unofficial agencies which will link up all development and welfare plans with community education, setting specific targets and attempting to imbue all groups and persons in the community with a sense of common effort and advantage. From some points of view the term 'mass education' as applied to such a programme is unfortunate. The objective is in fact the reverse of mass treatment. An articulate and appropriately differentiated community is the goal. The approach needs to be based in every case on the particular needs and opportunities in the given community and the activities of different persons and groups adjusted to their special functions, actual or potential. While the rapid promotion of literacy is an important aim, it is properly regarded as but the means to general advancement. The measures envisaged would not herd masses of adults into classes merely for reading and writing. It is community education in the widest sense that is urged; and that term, rather than one which suggests undifferentiated handling by uniform means, better expresses both the aims and the methods to be employed.

In framing the programme for any community, 'sociological mapping', together with a definition of the major obstacles to social and especially economic progress, which could provide the focus of public interest for an educational campaign, are held to be prerequisite. It is also urged that every advantage should be taken of existing educational agencies, formal and informal, and every attempt made to enlist the co-operation of indigenous organizations. In this connexion the point might well have been made that the very process of associating diverse organizations in a comprehensive scheme should have considerable educational value in promoting an awareness of social forces and a capacity to consider social organization in terms of practical needs. Organizations, whether indigenous or implanted, from secret societies and age-sets to mission units and village councils, will tend to be judged according to the service they can render. The need for preliminary survey whereby those in charge can secure a sound grasp of the social structure of the community in question is repeatedly emphasized: "however good the content of a mass education plan and its technique may be, it cannot hope to be successful unless it is carried out by people who know their society and its significant sociological forms and how they are changing under modern conditions". An essential point in the suggested organization is the appointment of "Mass Education Officers" to co-ordinate and supervise the work in any one area. Although not recruited from any one source, they will need training, as well as flair and interest, for understanding and securing the co-operation of the community in each project, and then guiding the development to promote social cohesion and welfare.

This point is perhaps one which needs particular attention, since it is but one instance of a growing need for investigators and executants with sociological training, for which there is at present only the most meagre provision in British educational institutions. The notion that training is required for independent and empirical inquiry into social structures and the forces that sustain them, and even that such inquiries are pre-requisite for intelligent control of social development, has yet to make its way. The relevance of sociological theory and field methods to the practical problems of politics and social development finds little recognition. A sense of history, a sound ethical code and a fair mind, on which the British traditions of public administration and social reform insist, are no doubt admirable qualities, but they do not dispense with the need for methodological safeguards against misconceptions and unconscious prejudice, or for the application of scientific knowledge of social processes. Our engineers and medical men are expensively trained to acquire a body of tested principle, a capacity for diagnosis and the ability to apply their knowledge to particular problems. Sociological principles and methods are left to filter indirectly and belatedly into our educational system. In questions of social policy, standards of careful investigation and logical analysis are often lacking. The accelerated pace of social change in colonial dependencies, involving as it does many societies generically distinct in type, is focusing attention on this need in a field in which the social anthropologists have already pioneered; but sociological training and research will have to be further developed on a very considerable scale if recommendations such as those of this report are to be implemented.

WÖHLER'S 'SYNTHETIC' UREA AND THE REJECTION OF VITALISM: A CHEMICAL LEGEND

By DR. DOUGLAS McKIE
University College, London

THAT Wöhler synthetized urea in 1828 and thereby rang the death-knell of vitalism in organic chemistry seems to be as firmly established a legend as that Galileo let fall at one and the same time from the leaning tower at Pisa two unequal weights, the thud of the simultaneous arrival of which upon the ground rang out the old Aristotelianism and rang in the new mechanics. But, as in the earlier, so in the later case, the facts are otherwise: there was no synthesis of urea, and chemists continued to assert the existence of vital force and to describe its role in the formation of organic substances. Wöhler's experiments have, however, acquired an altogether inexplicable and widespread significance, both in text-books and in popular scientific works, especially among those whose statements show that they cannot possibly have referred to his own account of them.

Wöhler published his memoir, "Ueber künstliche Bildung des Harnstoffs", in 1828[1]. We can scarcely call it well-known, because of the wide difference between what it contains and what its contents are now commonly believed to imply. In it Wöhler began by stating that he had returned to the study of the white crystalline substance that he had previously reported to be one of the products of the reaction between cyanogen and 'liquid ammonia' (that is, aqueous ammonia). This substance, as he had already pointed out, was produced also when one tried to combine cyanic acid with ammonia by double decomposition. It was more easily obtained either by the reaction between silver cyanate and a solution of sal ammoniac or by that between lead cyanate and 'liquid ammonia'. It was the product of the last reaction that was used for the experiments now reported by Wöhler. In the process of purification, the white crystalline substance appeared to give rise to a new product, which proved to be urea. Urea was, therefore, a compound of ammonia and cyanic acid; and an organic substance, in fact an animal substance, appeared to have been produced from inorganic materials. At that time, the cyanates were regarded as inorganic—of which more will be said later.

It was clear that the new substance was not an ammonium salt, as it yielded no ammonia with potash or with lime; and it no longer behaved as a cyanate on the addition of acids, nor did it precipitate lead or silver salts. Therefore, it contained neither ammonia nor cyanic acid: it was not ammonium cyanate. It possibly resembled a salifiable vegetable base. It behaved indifferently with acids, except nitric acid, the addition of which to a concentrated solution of the new substance gave a precipitate of shining scales, purification of which showed them to be so acid in character that Wöhler almost concluded that he had obtained a particular acid ("eine eigenthümliche Säure"), until he found that on neutralization with bases they gave nitrates from which the original substance could be separated by means of alcohol with all the properties that it had before the action of nitric acid. Comparative experiments with pure urea from urine showed that urea and the new substance were identical.

Prout's analysis of urea, Wöhler pointed out, closely corresponded with calculation from his own formula for ammonium cyanate together with an 'atom' of water. So, before discovering the formation of urea by cyanic acid and ammonia, it was possible to calculate in advance that ammonium cyanate with an 'atom' of water had the same composition as urea. Combustion of cyanic acid (by means of copper oxide) gave 2 volumes of carbonic acid and 1 volume of azote (nitrogen); but the combustion of ammonium cyanate should give equal volumes of these gases, which was what Prout found for the combustion of urea. Wöhler stated, in conclusion, that he refrained from all considerations on the subject of compounds of the same composition with very different properties, such as were already recognized in the case of fulminic acid and cyanic acid, and of "liquid carbonated hydrogen" and olefiant gas.

So ended this now famous paper, the contents of which, it will be seen, bear little relation to what is widely current about it. It contains nothing to justify any of the *décors* of death-knells and so on. Contemporary versions of it appeared in French[2] and in English[3]. They were careful and exact. The French version was a full and unexceptionable translation, including even the correction of a numerical error in the addition of the analytical data quoted from Prout. The English version was more in the nature of a detailed abstract, omitted nothing important, and was substantially complete.

Wöhler, therefore, records no synthesis; for by synthesis we mean the compounding of a substance from the elements that compose it. Cyanogen had not been synthetized at that time. The source and method of preparation of the cyanates are therefore of interest here. Organic matter, such as dried blood, hoofs, horns and so on, was heated with potash and iron; the resulting mass, on extraction with water, gave 'ferrocyanate of potash' (potassium ferrocyanide), from which by the action of heat there was obtained 'cyanuret of potassium' (potassium cyanide), which on oxidation gave the cyanate[4]. Among the hoofs, the cloven one of vitalism is surely not difficult to detect here (or in the 'liquid ammonia').

Wöhler wrote to Berzelius from Berlin on February 22, 1828, about these experiments and their curious results, saying that he could make urea without a kidney or a living creature, be it man or dog: ". . . ich Harnstoff machen kann, ohne dazu Nieren oder überhaupt ein Thier, sey es Mensch oder Hund, nöthig zu haben"[5]. Without a kidney or a living creature, man or dog: but, be it noted, not without dried blood, horns, hoofs, and such "organic" originals.

Yet Wöhler recognized in this very letter that the production of an organic substance from inorganic materials, or, as we should say, from non-living sources, turned on the question of the carbon used:

"Diese künstliche Bildung von Harnstoff, kann man sie als ein Beispiel von Bildung einer organischen Substanz aus unorganischen Stoffen betrachten? Es ist auffallend, dass man zur Hervorbringung von Cyansäure (und auch von Ammoniak) immer doch ursprünglich eine organische Substanz haben muss, und ein Naturphilosoph würde sagen, dass sowohl aus der thierischen Kohle, als auch aus den daraus gebildeten Cyanverbindungen, das Organische noch nicht verschwunden, und daher immer noch ein organischer Körper daraus wieder hervorzubringen ist"[6].

From Stockholm Berzelius replied on March 7, 1828, whetting his Rabelaisian wit upon the moderate and guarded claims of his devoted pupil and correspondent:

"Nachdem man seine Unsterblichkeit beim Urin angefangen hat, ist wohl aller Grund vorhanden, die Himmelfahrt in demselben Gegenstand zu vollenden, —und wahrlich, Hr. Doktor hat wirklich die Kunst erfunden, den Richtung zu einem unsterblichen Namen zu gehen. Aluminium[7] und künstlicher Harnstoff, freilich zwei sehr verschiedene Sachen, die so dicht aufeinander folgen, werden, mein Herr! als Edelsteine in Ihren Lorbeerkranz eingeflochten werden, und sollte die Quantität des artificiellen nicht genügen, so kann man leicht mit ein wenig aus dem Nachttopf supplieren. Sollte es nun gelingen, noch etwas weiter im Produktionsvermögen zu kommen (vesiculae seminales liegen ja weiter nach vorn als die Urinblase), welche herrliche Kunst, im Laboratorium der Gewerbeschule ein noch so kleines Kind zu machen.—Wer weiss? Es dürfte leicht genug gehen.—Aber nun genug mit Raillerie, besonders da ich es so eilig habe, nur Verständiges im Jahresbericht zu schreiben. Es ist eine recht wichtige und hübsche Entdeckung, die Hr. Doktor gemacht hat, und es machte mir ein ganz unbeschreibliches Vergnügen, davon zu hören. Es ist ein ganz sonderbarer Umstand, dass die Salznatur so vollständig verschwindet, wenn die Säure und das Ammoniak sich vereinigen, was für künstige Theorien sicher sehr aufklarend sein wird. . . ."[8].

Berzelius would not appear to have sensed any refutation of vitalistic belief here, nor in fact is there any: to regard the cyanates as inorganic substances was a mere item of code, especially in view of what has already been pointed out above about their mode of preparation; and, in any event, Wöhler had effected a transformation, not a synthesis.

Consideration of syntheses, real or imaginary, merely from the point of view of their significance for or against vitalistic theory, is not the most profitable historical study. Compounds other than those of carbon, for example, water and ammonia, might have to be considered; and among the carbon compounds themselves carbon dioxide might easily claim very serious consideration, above all things as the great medium between 'dead' and 'living' carbon. Logicians would probably seize on the very objection foreseen by Wöhler, namely, the necessity of knowing the pre-history of the carbon used in the crucial synthesis; and the geologists would not be prepared to vouch even for diamond as derived from 'non-living' origins. But chemists happily are not mere logicians; and it is of some interest for us to consider what organic substance was first synthetized (that is, compounded from its elements), the term 'organic substance' being used in the sense of an organic compound more complex than carbon dioxide occurring in, or produced by, living organisms. For this we must, it seems, turn to the synthesis of acetic acid by Wöhler's pupil, Kolbe.

In his historic memoir, "Beiträge zur Kenntniss der gepaarten Verbindungen"[9], Kolbe dealt with chloracetic acid towards the end[10] of his long discussion of copulated compounds. Using modern nomenclature and formulæ, we may readily summarize his work on this point. Carbon disulphide (made by heating charcoal and sulphur) reacted with chlorine to give tetrachlormethane, which, when passed as vapour through a red-hot tube, gave chlorine and tetrachlorethylene, which, in sunlight in the presence of water (and the free chlorine), gave trichloracetic acid. Melsens had shown a year earlier[11] that trichloracetic acid could be reduced to acetic acid by potassium amalgam. Thus the synthesis of acetic acid was complete. It was the achievement of Kolbe in 1845; it was the first organic substance to be synthetized; and it will soon be a hundred years since this notable work was published.

$$C + S \rightarrow CS_2 \rightarrow CCl_4$$

$$2CCl_4 \xrightarrow{\text{vapour in red-hot tube}} C_2Cl_4 + 2Cl_2$$

$$C_2Cl_4 + Cl_2 + 2H_2O \xrightarrow{\text{sunlight}} CCl_3COOH + 3HCl$$

$$CCl_3COOH \xrightarrow{H} CH_3COOH.$$

Those who are further interested in these matters may feel that both urea and acetic acid are what are called 'degradation' products of the living organism, but here we are content to have made some attempt to lay the legend of Wöhler's 'synthesis'. To most chemists, the facts seem to be known: they were taught to me as an undergraduate by Norman Collie, and it is clear that undergraduates at Manchester were also taught the true facts of the matter by Schorlemmer in the last century[12].

But what of vitalism after Wöhler's memoir of 1828? A study of the literature shows that Wöhler's experiments had no such result as they are now commonly credited with. In the 1840's, Berzelius, Wöhler's own teacher, then about to leave the scene of his prodigious chemical labours, and Gerhardt, at the zenith of his brilliant re-ordering of organic chemistry, both expressed their belief in the existence of a vital force in the formation of organic substances. In Berzelius's great treatise, in fact in the posthumous edition edited by Wöhler, he wrote:

"Dans la nature vivante, les éléments paraissent obéir à des lois tout autres que dans la nature inorganique; les produits qui résultent de l'action réciproque de ces éléments, diffèrent donc de ceux que nous présente la nature inorganique. Si l'on parvenait à découvrir la cause de cette différence, on aurait la clef de la théorie de la chimie organique. Mais cette théorie est tellement abstruse, que nous n'avons aucun espoir de la découvrir, du moins quant à présent. Néanmoins nous devons faire des efforts pour en approcher; car nous finirons par y arriver, ou bien nous serons arrêtés à une limite que nos investigations ne sauraient dépasser . . . l'essence du corps vivant ne repose pas sur ses éléments inorganiques, mais sur quelque autre principe, qui porte les éléments inorganiques communs à tous les corps vivants à coopérer à la production d'un résultat particulier, déterminé et différent pour chaque espèce.

"Ce principe (que nous désignons par le nom de *force vitale* ou *assimilatrice*) n'est pas inhérent aux éléments inorganiques, et ne constitue pas une de leurs propriétés primordiales, telle que la pesanteur, l'impénétrabilité, la polarité électrique, etc.; mais nous ne saurions concevoir en quoi il consiste, comment il prend naissance, comment il finit. Nous pouvons donc prévoir que si le globe terrestre existait avec ses éléments inorganiques, sans la nature vivante, mais du reste dans les mêmes circonstances, il continuerait à subsister sans êtres organisés. Une force incompréhensible, étrangère à la nature morte, a introduit ce principe dans la masse inorganique . . ."[13].

This was followed by a long and highly teleological comment. The ideas expounded by Berzelius on this problem have recently been described by Delacre as "presque un cours de morale"[14]. From our present point of view, we can at least surely say that those who believe that Wöhler drove vitalism out of organic chemistry will believe anything.

Gerhardt was at even greater pains to make his views on this matter clear and precise. In the summary of his classic memoir, "Recherches sur la classification chimique des substances organiques", read to the Paris Academy of Sciences in 1842, he said:

"J'y démontre que le chimiste fait tout l'opposé de la nature vivante; qu'il brûle, détruit, opère par analyse; que la force vitale seule opère par synthèse; qu'elle reconstruit l'édifice abattu par les forces chimiques"[15].

In the full-dress version of this, his most famous memoir, Gerhardt pictured all "êtres organisés vivants" as subject to two opposing forces, vital force and chemical affinity, normally in a state of dynamical equilibrium. He wrote:

"Si cet état d'équilibre était durable, si l'agent vital n'était jamais vaincu par les forces chimiques, on ne sait trop quelle serait la destinée des êtres organisés; mais sans doute alors la mort serait impossible, puisque la mort est précisément la cessation de toute résistance de la part de l'organisme contre les influences chimiques"[16].

The equilibrium is not abruptly upset: disease produces abnormal conditions locally and leads to the triumph of the chemical forces and the death of the organism. The action of the chemical forces on the organism leads to the production of carbonic acid, water, urea, and so on, but these are products of decomposition; and it is precisely these originals that the vital force acts upon in the contrary sense to build up blood and brain matter in animals, and wood fibres in plants. Gerhardt, indeed, held that the chemist could no more succeed in this re-building than the alchemist could attain an aim that seems less difficult:

"En présence de ces belles découvertes et de tout d'autres dont la chimie organique s'est enrichie depuis ces dernières années, celui qui ne considérerait que le fait de la reproduction artificielle, sans avoir connaissance des procédés, serait presque tenté d'attribuer au chimiste un pouvoir surnaturel, un pouvoir magique. A le voir ainsi enfanter, dans ses cornues et ses creusets, les créations de la nature vivante, pourquoi, en effet, ne lui accorderait-on pas la puissance de transmuter les métaux et de faire de l'or, ce qui semble cependant moins difficile? Une observateur superficiel pourrait seul se bercer de ce fol espoir"[17].

The chemist had never regenerated uric acid from urea, sugar from alcohol, and so on; and he would ever lack that power. Here Gerhardt repeated the assertion that he had made before the Academy and which I have quoted above: "La force vitale seule opère par synthèse". He went on to imagine an immense scale or ladder of organic substances. At its summit were such complex substances as the matter of the brain, blood, and so on; at its base, the much simpler substances, water, carbonic acid, urea, into which those more complex substances higher in the scale were decomposed by the action of chemical affinity, whereas, by the action of vital force, the simpler substances were again built up into the more complex.

Yet, when Wöhler died in 1882 and Hofmann prepared an account of his work, history had already begun to be written backwards as if it, too, were a 'reversible' process; and Hofmann spoke of Wöhler's 'synthesis' of urea as "an epoch-making discovery in the real sense of that word", explaining that chemists could scarcely realize the impression that the building up of urea from its elements ("aus seinen Elementen"!) then made on men's minds nor could they "conceive the feeling of joy with which the gospel of a new unified chemistry was hailed by the intellect of that time":

"Die Synthese des Harnstoffs ist im eigentlichen Sinne des Wortes eine epochemachende Entdeckung. Mit ihr war der Forschung ein neues Gebiet erschlossen, von welchem die Chemiker nicht zögerten Besitz zu ergreifen. Die heutige Generation . . . kann sich nur schwer in jene entfernten Zeiten zurückversetzen, denen das Zustandekommen einer organischen Verbindung im Körper der Pflanze oder des Thieres in geheimnissvoller Weise von der Lebenskraft bedingt erschien, und sie vermag sich daher auch kaum den Eindruck zu vergegenwärtigen, welchen der Aufbau des Harnstoffs aus seinen Elementen auf die Gemüther hervorbrachte . . . und man begreift daher den Jubel, mit welchem die Botschaft einer neuen einheitlichen Chemie von den Geistern begrüsst ward"[18].

It is difficult to make any comment on this extraordinary assertion; it appears to have been written without any sense of history or of restraint.

Vitalism in organic chemistry was rejected, not by any sudden and dramatic synthesis—for science does not advance and Nature does not reveal herself in that way—but by steady accumulation of contradictory fact: and in this field it seems remarkably odd that the professor of chemistry in Berlin should not have thought of that great chemist, great scholar and great Frenchman, Marcellin Berthelot, by whose discoveries, the earlier of which had been published more than twenty years previously, in 1860, in his classic "Chimie organique fondée sur la Synthêse", that rejection was ultimately achieved and from whom it unquestionably derives.

[4] The process is described in the almost contemporary text-book of Edward Turner, the first professor of chemistry in University College, London: "Ferrocyanate of potash" is "made on a large scale in the arts by igniting dried blood or other animal matters, such as hoofs and horns, with potash and iron. By the mutual reaction of these substances at a high temperature, ferrocyanuret of potassium, consisting of one equivalent of the radical of ferro-cyanic acid . . . and two equivalents of potassium, is generated. Such at least is inferred to be the product; for on digesting the residue in water, a solution of ferrocyanate of potash is obtained. . . . When heated to 212° F., or even below that temperature, each equivalent of the salt parts with three equivalents of water, leaving one equivalent of ferrocyanuret of potassium. . . . On heating the dry compound to full redness in close vessels, decomposition takes place, nitrogen gas is disengaged, and cyanuret of potassium mixed with carburet of iron remains in the retort." ("Elements of Chemistry, etc.", 3rd edn.. 658; London, 1831).

A NATIONAL ADVISORY SERVICE FOR AGRICULTURE AND HORTICULTURE

By H. W. MILES
Research Station, Long Ashton

In a statement in Parliament on January 20, dealing with the future of agricultural education, the Minister of Agriculture said that after careful consideration of the Luxmoore Report the Government has concluded that the provincial and county agricultural advisory services should be unified and combined into one national service for the whole country, directly under the Minister of Agriculture and financed wholly by the Exchequer. This statement, together with the publication of the Luxmoore Report, has concentrated attention on the organization and function of the existing agricultural advisory services and on how far the proposals of the Luxmoore Committee would strengthen and unify them. This subject was discussed at a recent meeting of the Association of Applied Biology, when Prof. W. B. Brierley was the principal speaker.

In the early stages of the development of agricultural education in England and Wales, most farmers regarded scientific agriculture with suspicion, and had little inclination to seek the help of technical advisers for the solution of farming problems. At first only formal courses of instruction for young people were available, and later lectures and demonstrations were provided for farmers. Prejudice hampered development and by 1908 only eight counties had appointed full-time agricultural organizers. In 1908 a departmental committee investigated the position of agricultural education in England and Wales, and recommended that each area the size of an average county should have a resident agricultural organizer to give instruction to farmers, to arrange field experiments, to lecture on their results and other matters of agricultural interest, and to act as director of agricultural education. Since then county agricultural staffs have been increased and now include instructors for crop production and animal husbandry, horticulture, dairying and poultry-keeping, who are well qualified to give advice on all practical difficulties. The county agricultural service has been controlled by the local county council and financed partly from rates and partly by the Ministry of Agriculture.

With the establishment of the Development Commission in 1909, money was made available for new developments in agricultural research and for the extension of advisory and teaching services. New research institutes were founded and financial assistance was given to those already in existence. In order that farming practice should be influenced by the extension of research work it was necessary to provide some bridge for the gap between the scientific work of the research institutes and the practical advisory work of county technical staffs. In 1911 it was decided to make annual payments from the Development Fund to certain universities and agricultural colleges to enable them to supply specialist advice to farmers and to provide for the investigation of local agricultural problems. This new specialist advisory service was organized on a provincial basis, and thirteen provinces covered England and Wales. The provincial advisory staffs were appointed, accommodated and administered by universities and agricultural colleges, which in return were allowed to call upon the advisers for a limited amount of teaching. The number of advisers varied with the demands of the provinces but usually included advisers in entomology, mycology, chemistry, economics and veterinary science. A memorandum of the Board of Agriculture ($A\frac{200}{1}$) defined the nature and scope of the two agricultural advisory services. Advice on such practical matters as the uses of artificial fertilizers, the relative merits of feeding stuffs for livestock and the manufacture of dairy produce should be given by the county staff. Advice on matters requiring special knowledge or special investigation should be given by the staffs of universities and agricultural colleges. County staffs were recommended to refer such problems to specialists and to consult the staffs of universities and colleges when their scientific knowledge and experience would be helpful.
